

## CONVERGENCE RATES IN FORWARD–BACKWARD SPLITTING\*

GEORGE H.-G. CHEN<sup>†</sup> AND R. T. ROCKAFELLAR<sup>‡</sup>

**Abstract.** Forward–backward splitting methods provide a range of approaches to solving large-scale optimization problems and variational inequalities in which structures conducive to decomposition can be utilized. Apart from special cases where the forward step is absent and a version of the proximal point algorithm comes out, efforts at evaluating the convergence potential of such methods have so far relied on Lipschitz properties and strong monotonicity, or inverse strong monotonicity, of the mapping involved in the forward step, the perspective mainly being that of projection algorithms. Here, convergence is analyzed by a technique that allows properties of the mapping in the backward step to be brought in as well. For the first time in such a general setting, global and local contraction rates are derived; moreover, they are derived in a form which makes it possible to determine the optimal step size relative to certain constants associated with the given problem. Insights are thereby gained into the effects of shifting strong monotonicity between the forward and backward mappings when a splitting is selected.

**1. Introduction.** This paper concerns a class of numerical methods for finding solutions to variational inequalities and other “generalized equations,” especially in circumstances where a need for decomposition into simpler subproblems is apparent. Optimization problems fit the framework of these methods through the ways that variational inequalities can express first-order optimality conditions in primal, dual, or primal–dual form. Variational inequalities serve also in models of equilibrium and a diversity of other applications.

In general, the *variational inequality* problem for a closed convex set  $C \subset \mathbb{R}^n$  and a continuous mapping  $F : C \rightarrow \mathbb{R}^n$  looks for a vector  $\bar{x}$  such that

$$(1.1) \quad 0 \in T(\bar{x}) \quad \text{for} \quad T(x) = F(x) + N_C(x),$$

where  $N_C(x)$  is the set-valued normal cone mapping associated with  $C$ :

$$(1.2) \quad N_C(x) = \begin{cases} \{w \in \mathbb{R}^n \mid \langle w, x' - x \rangle \leq 0 \text{ for all } x' \in C\} & \text{when } x \in C, \\ \emptyset & \text{when } x \notin C, \end{cases}$$

with  $\langle \cdot, \cdot \rangle$  denoting the canonical scalar product of vectors. The variational inequality problem is a *complementarity* problem when  $C = \mathbb{R}_+^n$ . Especially important is the case where  $F$  is *monotone* on  $C$ , in the sense that

$$(1.3) \quad \langle F(x') - F(x), x' - x \rangle \geq 0 \quad \text{for all } x, x' \in C,$$

which in the optimization setting characterizes problems of convex type. Then the set-valued mapping  $T$  is itself monotone:

$$(1.4) \quad \langle w' - w, x' - x \rangle \geq 0 \quad \text{whenever } w \in T(x), w' \in T(x').$$

In fact, it is *maximal* monotone—its graph set  $\{(x, w) \mid w \in T(x)\}$  can't be enlarged without destroying monotonicity.

Forward–backward splitting methods are versatile in offering ways of exploiting the special structure of variational inequality problems. Following Lions and Mercier [1], such methods can be posed broadly in terms of solving

$$(1.5) \quad 0 \in T(\bar{x}) \quad \text{when} \quad T(x) = T_1(x) + T_2(x)$$

for any mapping  $T$  that associates with each  $x \in \mathbb{R}^n$  a (possibly empty) set  $T(x) \subset \mathbb{R}^n$ , a situation we symbolize by  $T : \mathbb{R}^n \rightrightarrows \mathbb{R}^n$ , and any representation of  $T$  as a sum of two other such mappings  $T_1$  and  $T_2$ . The representation  $T = T_1 + T_2$ , which might be set up in a multitude of different ways, is called a *splitting* of  $T$ . From an initial point  $x_0$ , a point  $x_k$  is generated in each iteration  $k$  for  $k = 1, 2, \dots$  by solving the subproblem

$$(1.6) \quad 0 \in (T_{1k} + T_2)(x_k) \quad \text{with} \quad T_{1k}(x) = T_1(x_{k-1}) + \frac{1}{\lambda_k} H_k[x - x_{k-1}]$$

for a *step size* value  $\lambda_k > 0$  and an *implementation matrix*  $H_k \in \mathbb{R}^{n \times n}$ . Under the license of denoting the linear mapping  $x \mapsto H_k x$  by the same symbol  $H_k$ , the iterations can be written in the form

$$(1.7) \quad x_k \in S_k(x_{k-1}) \quad \text{for} \quad S_k = (H_k + \lambda_k T_2)^{-1}(H_k - \lambda_k T_1).$$

The *forward–backward* name comes from the fact that (as long as  $H_k$  is nonsingular) the iteration mapping  $S_k$  has the equivalent expression

$$S_k = (I + \lambda_k H_k^{-1} T_2)^{-1}(I - \lambda_k H_k^{-1} T_1).$$

In the language of numerical analysis,  $I - \lambda_k H_k^{-1} T_1$  gives a *forward* step with step size  $\lambda_k$  and direction vector  $d_k = -H_k^{-1} u_k$ ,  $u_k \in T_1(x_k)$  (or  $u_k = T_1(x_k)$  when  $T_1$  is single valued), whereas  $(I + \lambda_k H_k^{-1} T_2)^{-1}$  gives a *backward* step. Implementations where  $H_k$  is symmetric and positive definite are central, but weaker requirements are of interest in some situations.

For the purpose of solving a variational inequality (1.1), forward–backward splitting methods can be applied to

$$(1.8) \quad T = F + N_C, \quad T_1 = F_1, \quad T_2 = F_2 + N_C, \quad \text{with} \quad F = F_1 + F_2$$

for a choice of continuous mappings  $F_1 : C \rightarrow \mathbb{R}^n$  and  $F_2 : C \rightarrow \mathbb{R}^n$ . The iterations mean then that  $x_k$  is determined by solving

$$(1.9) \quad 0 \in T_k(x_k) \quad \text{for} \quad \begin{aligned} T_k(x) &= (F_{1k} + F_2)(x) + N_C(x) \quad \text{with} \\ F_{1k}(x) &= F_1(x_{k-1}) + \frac{1}{\lambda_k} H_k[x - x_{k-1}]. \end{aligned}$$

This covers many numerical procedures, the most familiar among them being ones that correspond to the splitting choices where either  $F_1 = F$ ,  $F_2 = 0$ , or, at the other extreme,  $F_1 = 0$ ,  $F_2 = F$ .

For the splitting where  $F_1 = F$  and  $F_2 = 0$  in (1.8), so that  $T_1 = F$  and  $T_2 = N_C$ , the forward–backward iterations with symmetric, positive definite  $H_k$  give a *projection algorithm* (of possibly “variable metric” type):  $x_k$  is the point of  $C$  nearest to

$$(1.10) \quad x'_k = x_{k-1} - \lambda_k H_k^{-1} F(x_{k-1}),$$

with respect to the norm induced by  $H_k$ . Indeed, (1.9) can be written in terms of (1.10) as the relation  $-H_k[x_k - x'_k] \in N_C(x_k)$ , which is necessary and sufficient for having

$$(1.11) \quad x_k = \operatorname{argmin}_{x \in C} \langle [x - x'_k], H_k[x - x'_k] \rangle.$$

Of course, if  $C = \mathbb{R}^n$  then the projection trivializes and there's no backward step, just a forward step: one has  $x_k = x_{k-1} - \lambda_k H_k^{-1} F(x_{k-1})$ .

Among projection algorithms (1.9)–(1.10), the *gradient* case  $F = \nabla f$  is the best known. If  $H_k = I$ , a variant of Cauchy's method is obtained, whereas if  $H_k$  is taken to be an approximation to  $\nabla F(\bar{x}) = \nabla^2 f(\bar{x})$ , a form of Newton's method comes out. Gradient projection algorithms were first studied in the Cauchy form by Goldstein [2] and in the Newton form by Levitin and Polyak [3], and they have since generated a large literature in optimization. For general variational inequalities, projection algorithms go back to Brézis and Sibony [4]; see also Sibony [5], Gajewski and Kluge [6], and for early developments attuned to mathematical programming, especially Dafermos [7].

For the other extreme splitting in (1.8), where  $F_1 = F$  and  $F_2 = 0$  so that  $T_1 = 0$  and  $T_2 = F + N_C$ , the forward–backward procedure specializes to backward steps only and thus turns into (a “variable metric” form of) the *proximal point algorithm* for the mapping  $T = F + N_C$ . The proximal point algorithm was developed as a numerical method by Rockafellar [8], [9] in the case of  $H_k \equiv I$  or, equivalently,  $H_k \equiv H$  symmetric and positive definite, since that differs only in the designation of the norm (the context being one of a Hilbert space anyway). This algorithm is known to include, through various special choices, many other schemes such as generalized Douglas–Rachford splitting, cf. Eckstein and Bertsekas [10], and Spingarn splitting [11], which apply to maximal monotone mappings  $T$  not just of the variational inequality type in (1.1). An illuminating overview of splitting methods of all kinds has been provided by Eckstein [12].

Forward–backward splitting is closely related to an algorithmic approach introduced by Cohen as the “auxiliary problem principle” for problems of optimization in [13], [14], and variational inequalities in [15]. Cohen's formulation allows for the replacement of the linear implementation mapping  $x \mapsto H_k x$  by a kind of nonlinear mapping, an idea treated also by Pang and Chan [16], among others. Patriksson [17] has explored this possibility broadly, showing how a vast array of known procedures can thereby be put into the framework of forward–backward methods.

Our focus in this paper is on the general iterations (1.7) for splittings  $T = T_1 + T_2$  with  $T_1$  single valued in which  $T$ ,  $T_1$ , and  $T_2$  are monotone and both  $T_1 \not\equiv 0$  and  $T_2 \not\equiv 0$ , so that nontrivial forward steps as well as nontrivial backward steps can be expected. In the variational inequality context this corresponds to splittings of type (1.8) in which  $F$ ,  $F_1$ , and  $F_2$  are monotone and  $F_1 \not\equiv 0$ . We aim in particular at an understanding of convergence in cases where  $F_2 \not\equiv 0$  too, so that more than a projection algorithm is involved. Such forms of forward–backward splitting methods are suggested by the decomposition needs of large-scale optimization problems with dynamic or stochastic structure [18], [19], [20] or PDE structure [21], but they haven't previously received much attention.

Except in connection with a weak ergodic type of convergence, cf. Passty [22], most of the research on general forward–backward splitting methods has relied on assumptions of strong monotonicity. Recall that a mapping  $T : \mathbb{R}^n \rightrightarrows \mathbb{R}^n$  is *strongly*

monotone if there is a constant  $\mu > 0$  such that

$$(1.12) \quad \langle w' - w, x' - x \rangle \geq \mu \|x' - x\|^2 \quad \text{whenever} \quad w \in T(x), w' \in T(x')$$

or, equivalently, the mapping  $T - \mu I$  is monotone. By the same token the inverse mapping  $T^{-1}$ , defined by taking  $x \in T^{-1}(w)$  to mean that  $w \in T(x)$ , is strongly monotone if there is a constant  $\nu > 0$  such that

$$(1.13) \quad \langle w' - w, x' - x \rangle \geq \nu \|w' - w\|^2 \quad \text{whenever} \quad w \in T(x), w' \in T(x').$$

The strong monotonicity of  $T^{-1}$  is sometimes called the *Dunn* property or the *co-coercivity* of  $T$ . If  $T$  is single valued and Lipschitz continuous with constant  $\kappa$  and strongly monotone with constant  $\mu$ , then  $T^{-1}$  is strongly monotone with constant  $\nu = \mu/\kappa^2$ .

For implementations with  $H_k \equiv I$  and  $\lambda_k \equiv \lambda$ , Gabay [23] showed that if  $T_1$  is single valued and maximal monotone with constant  $\mu_1$  as well as Lipschitz continuous with constant  $\kappa_1$ , the sequence of iterates  $x_k$  generated from any starting point  $x_0$  converges to the unique solution  $\bar{x}$  to (1.1), as long as  $0 < \lambda < 2\mu_1/\kappa_1^2$ . Alternatively he obtained convergence by assuming that a solution exists and  $T_1^{-1}$  is strongly monotone with constant  $\nu_1$  (which entails  $T_1$  being Lipschitz continuous with constant  $1/\nu_1$ ) and by taking  $0 < \lambda < 2\nu_1$ . Tseng [24] extended the latter result to nonconstant step sizes  $\lambda_k$  and used it in that paper and in [25] to verify convergence for some schemes of problem decomposition. Further work in this vein, allowing for nonlinear implementation mappings and even for the approximation of  $T_1$  and  $T_2$  by mappings  $T_1^k$  and  $T_2^k$  in iteration  $k$ , was carried out to a certain degree by Mouallif, Nguyen, and Strodiot [26] and Makler-Scheinberg, Nguyen, and Strodiot [27].

In the special case of projection algorithms, Dafermos in [7] obtained Q-linear convergence as a consequence of deriving a global contraction rate for the iterations (1.10)–(1.11). She did this for a fixed matrix  $H_k \equiv H$ , possibly different from  $I$ , employing the  $H$ -norm

$$(1.14) \quad \|x\|_H = \sqrt{\langle x, Hx \rangle}$$

and its dual instead of the canonical norm  $\|x\|$ . She determined the fixed step size  $\lambda_k \equiv \lambda$  for which the contraction rate would be optimal relative to constants of Lipschitz continuity and strong monotonicity for  $F$  when estimated in a certain way. These results were sharpened for affine variational inequalities by Dupuis and Darveau [28]. Bertsekas and Gafni [29] demonstrated R-linear convergence, i.e.,

$$(1.15) \quad \limsup_{k \rightarrow \infty} \|x_k - \bar{x}\|^{1/k} < 1,$$

for the case where  $C$  is polyhedral but  $F$  is not itself strongly monotone, rather just of the form  $A^\top F_0 A$  for a strongly monotone mapping  $F_0$  and a matrix  $A$ . Zanni [30] showed that the rate estimates of Dafermos and of Bertsekas and Gafni could not be expected to support rapid convergence; as an alternative he developed for the affine case in [31] a change of variables which offers a substantial improvement. Renaud in his thesis [32] got a contraction rate based on strong monotonicity constants for both  $F$  and  $F^{-1}$ . Marcotte and Wu [33], in proceeding from Tseng [25] and Luo and Tseng [34], proved linear convergence when  $C$  is polyhedral and  $F$  is affine with  $F^{-1}$  strongly monotone. Tseng in [35] developed broad conditions for Q-linear convergence

of iterative methods which he applied to projection methods for affine variational inequalities without, however, dealing explicitly with rate estimates or step sizes. For a survey of solution methods for finite-dimensional variational inequalities more generally, see Harker and Pang [36].

Little was known until recently about linear rates of convergence in the general setting of forward-backward methods. Renaud [32] succeeded in demonstrating R-linear convergence (1.15), although not actual contraction, in circumstances where  $T_1^{-1}$  is strongly monotone while  $T$  exhibits strong monotonicity relative to a unique solution  $\bar{x}$ . In Chen's thesis [37], contraction rates were developed under a variety of hypotheses entailing strong monotonicity of  $T$ , and step size optimization relative to those rate estimates was carried out.

Our efforts here take off from [37] in directions pioneered by Dafermos [7], going further than she and through territory encompassing much more than just projection algorithms. We reach conclusions significantly stronger than those of Chen [37] in some respects.

For simplicity at the start, we concentrate in section 2 on a constant step size  $\lambda_k \equiv \lambda$  and a constant matrix  $H_k \equiv H$ , which we allow to differ from  $I$  but assume to be symmetric and positive definite. We work at establishing linear convergence in the strong sense of global contractivity of the mapping

$$(1.16) \quad S_\lambda = (H + \lambda T_2)^{-1}(H - \lambda T_1) = (I + \lambda H^{-1}T_2)^{-1}(I - \lambda H^{-1}T_1)$$

with respect to the norm  $\|\cdot\|_H$ . Thus, we seek  $\theta_\lambda \in [0, 1)$  such that  $\|S_\lambda(x') - S_\lambda(x)\|_H \leq \theta_\lambda \|x' - x\|_H$  for all  $x$  and  $x'$ , hence, in particular,

$$(1.17) \quad \|S_\lambda(x) - \bar{x}\|_H \leq \theta_\lambda \|x - \bar{x}\|_H \quad \text{for all } x.$$

We try to do this in such a manner that  $\theta_\lambda$  can be expressed in terms of estimated properties of the given problem, thereby opening the way to optimizing  $\theta_\lambda$  with respect to the choice of  $\lambda$  and obtaining some guidance on how  $\lambda$  might be selected in practice.

Obviously  $\alpha_{\min}\|x\| \leq \|x\|_H \leq \alpha_{\max}\|x\|$  for the lowest and highest eigenvalues  $\alpha_{\min}$  and  $\alpha_{\max}$  of  $H$ , so that linear convergence with respect to  $\|\cdot\|_H$  is equivalent to linear convergence with respect to  $\|\cdot\|$ . But the *rate* of linear convergence, as quantified by the size of the contraction factor, which is the crucial measure for numerical purposes, could be quite different in the two cases. By working with  $\|\cdot\|_H$  we are able to capture a better rate through finer tuning. This corresponds essentially to a change of variables in which we look at behavior in  $u = H^{-1/2}x$  instead of  $x$ , but our pattern is to proceed with the analysis directly in terms of  $x$ . More consistently than Dafermos and others in this subject, we avoid reference to the canonical norm  $\|\cdot\|$  so as to keep our results close to the natural geometry of the method and away from extraneous dependence on the condition number of  $H$  through appeal to the eigenvalues  $\alpha_{\min}$  and  $\alpha_{\max}$ . The philosophy is that if the condition number is to have any role at all, it should only be relative to a *one-time* change of variables, not a change to another norm and back again in every iteration, which is the unfortunate effect of bringing  $\alpha_{\min}$  and  $\alpha_{\max}$  into estimates of a contraction rate.

We utilize Lipschitz properties of  $T_1$ , but, in contrast to all previous research, we base the constant on a *residual* part of  $T_1$ , obtained by subtracting off the strong monotonicity that has been identified. We refer the Lipschitz constant to  $\|\cdot\|_H$  and the corresponding dual norm  $\|\cdot\|_{H^{-1}}$ . Likewise, we adapt our estimates of strong monotonicity to  $\|\cdot\|_H$  instead of  $\|\cdot\|$ .

Especially to be noted is that we don't insist on strong monotonicity of either  $T_1$  or  $T_1^{-1}$ . This is motivated by prospective applications to the large-scale problems cited in [18], [19], and [20]. Roughly, such problems follow the lines of minimizing  $f(x) + g(D(x))$  for proper lower semicontinuous (lsc) convex functions  $f$  and  $g$  and a mapping  $D$  like a discrete differential operator, integration operator, or expectation operator. The subgradient condition for  $\bar{x}$  to be optimal involves a dual element  $\bar{y}$  such that  $-D^\top \bar{y} \in \partial f(\bar{x})$  and  $D\bar{x} \in \partial g^*(\bar{y})$ , where  $g^*$  is the convex function conjugate to  $g$ . This condition can be written as

$$(1.18) \quad (0, 0) \in (T_1 + T_2)(\bar{x}, \bar{y}) \quad \text{for} \quad \begin{cases} T_1(x, y) &= (D^\top y, -Dx), \\ T_2(x, y) &= (\partial f(x), \partial g^*(y)), \end{cases}$$

and it thus corresponds to a problem in  $z = (x, y)$  that consists of solving  $0 \in T(\bar{z})$  in the presence of a splitting  $T = T_1 + T_2$  with  $T_1$  and  $T_2$  maximal monotone. Separability properties of  $f$  and  $g$ , reflected in a parallel choice of  $H$ , typically make it easy to iterate with  $(x_k, y_k) = S_\lambda(x_{k-1}, y_{k-1})$ , but  $T_1$  is an *antisymmetric* linear mapping, so that neither  $T_1$  nor  $T_1^{-1}$  can be strongly monotone. No results prior to ours could say anything substantial about convergence in this instance of a forward-backward splitting method. Note that (1.18) also gives incentive for not stopping at variational inequality models (1.8) in the treatment of such methods.

In section 3 we study the implications of our basic results for the ways that a splitting  $T = T_1 + T_2$  might be set up most advantageously. Applications are made to procedures for solving variational inequalities—in particular, projection algorithms. We show a better contraction rate than that of Dafermos [7] or the one of Dupuis and Darveau [28] for affine variational inequalities; the result resembles a recent one of Zanni [31] but goes further. The step size associated with our contraction rate has the remarkable property of automatically optimizing performance with respect to the possible shifts of strong monotonicity between  $T_1$  and  $T_2$ . The surprising result that as long as our step size prescription is followed any forward-backward method in the variational inequality case (1.8)–(1.9) can equally well be executed as a projection algorithm is thus achieved.

The global analysis of section 3 is supplemented in section 4 by a local analysis of convergence. Variable step sizes  $\lambda_k$  and implementation matrices  $H_k$  are taken up in section 5 and methods with asymmetric implementation matrices in section 6. For the literature on asymmetric implementations in solving variational inequalities, see Pang and Chan [16], Dafermos [38], Tseng [25], and Patriksson [17].

Because we are concerned with broad theoretical issues, we omit from the present study a number of refinements that could be pursued. The question of what happens when the subproblems in (1.6) or (1.9) are solved only approximately is not dealt with here, nor is the question of improvements based on augmenting the procedure with line search relative to some merit function. On the other hand, because we put our energy into the task of solving  $0 \in T(\bar{x})$  for mappings  $T$  not necessarily of the variational inequality form (1.1), we get results that apply equally well to problems where, for example as in (1.18), the normal cone mapping  $N_C$  in (1.1) may be replaced by the subgradient mapping associated with a possibly nonsmooth convex function.

**2. Global convergence analysis.** A mapping  $T$  that assigns to each  $x \in \mathbb{R}^n$  a set  $T(x) \subset \mathbb{R}^n$  (perhaps a singleton) is indicated by  $T : \mathbb{R}^n \rightrightarrows \mathbb{R}^n$ . The effective domain of such a mapping is the set  $\text{dom } T = \{x \mid T(x) \neq \emptyset\}$ . When  $T$  is maximal monotone,  $\text{dom } T$  is almost convex, in the sense that  $\text{cl}(\text{dom } T)$  is a convex set whose

relative interior lies within  $\text{dom } T$ ; cf. Minty [39]. The graph of  $T$  is considered to be the set of pairs  $(x, w)$  such that  $w \in T(x)$ , and the graph of  $T^{-1}$  consists therefore of the reversals  $(w, x)$  of all such pairs. The set of solutions  $\bar{x}$  to  $0 \in T(\bar{x})$  is  $T^{-1}(0)$ .

We investigate the feasibility of determining a solution  $\bar{x}$  through iterations  $x_k \in S_\lambda(x_{k-1})$  of the mapping in (1.16), as dictated by a choice of a splitting  $T = T_1 + T_2$ , a step size  $\lambda > 0$ , and an implementation matrix  $H$ . We don't suppose necessarily that  $T$  takes the variational inequality form in (1.1), but we do, for now, make the following assumptions.

**BASIC ASSUMPTIONS (A).** *The mapping  $T_2 : \mathbb{R}^n \rightrightarrows \mathbb{R}^n$  is maximal monotone, and the set  $\text{dom } T_2$ , denoted for simplicity by  $D$ , contains more than just one point (to avoid trivialities). The mapping  $T_1 : D \rightarrow \mathbb{R}^n$  is single valued, monotone, and Lipschitz continuous, so in particular the mapping  $T = T_1 + T_2$  has effective domain  $D$  like  $T_2$ . The matrix  $H \in \mathbb{R}^{n \times n}$  is symmetric and positive definite (hence nonsingular with  $H^{-1}$  symmetric and positive definite), while  $\mu_1$  and  $\mu_2$  denote constants such that*

$$(2.1) \quad \begin{cases} \text{the mappings } \tilde{T}_1 = T_1 - \mu_1 H \text{ and } \tilde{T}_2 = T_2 - \mu_2 H \text{ are} \\ \text{monotone on } D \text{ with } \mu_1 \geq 0, \mu_2 \geq 0, \mu_1 + \mu_2 > 0. \end{cases}$$

Furthermore,  $\tilde{\kappa}_1$  is a Lipschitz constant for  $\tilde{T}_1$  on  $D$  from  $\|\cdot\|_H$  to  $\|\cdot\|_{H^{-1}}$ :

$$(2.2) \quad \|\tilde{T}_1(x') - \tilde{T}_1(x)\|_{H^{-1}} \leq \tilde{\kappa}_1 \|x' - x\|_H \quad \text{for all } x', x \in D.$$

Here in parallel to (1.14) we use the notation  $\|w\|_{H^{-1}} = \sqrt{\langle w, H^{-1}w \rangle}$ . The norm  $\|w\|_{H^{-1}}$  is dual to the norm  $\|\cdot\|_H$ ; one has

$$(2.3) \quad \langle x, w \rangle \leq \|x\|_H \|w\|_{H^{-1}} \quad \text{for all } x, w \in \mathbb{R}^n.$$

Because monotone mappings must be interpreted technically as going from a vector space to its dual, it's natural in (2.2) to match the  $H$ -metric on the domain of  $\tilde{T}_1$  with the  $H^{-1}$ -metric on the range of  $\tilde{T}_1$ .

The monotonicity assumptions in (2.1) correspond (in the face of  $T_1$  being single valued on  $D = \text{dom } T_2$ ) to requiring that

$$\langle T_1(x') - T_1(x), x' - x \rangle \geq \mu_1 \langle x' - x, H[x' - x] \rangle \quad \text{for all } x, x' \in D,$$

$$\langle w' - w, x' - x \rangle \geq \mu_2 \langle x' - x, H[x' - x] \rangle \quad \text{whenever } w \in T_2(x), w' \in T_2(x').$$

Because  $\mu_1 + \mu_2 > 0$ , these inequalities combine to imply that  $T$  is strongly monotone with constant  $(\mu_1 + \mu_2)\alpha_{\min}$ , where  $\alpha_{\min}$  stands again for the lowest eigenvalue of  $H$ . But this constant of strong monotonicity won't come into play. We'll stay entirely with  $\mu_1$  and  $\mu_2$  as measures of monotonicity adapted to  $\|\cdot\|_H$  rather than to  $\|\cdot\|$ .

Assumptions (A) in the variational inequality case (1.1) (for a closed convex set  $C$  with more than one point and continuous mappings  $F_1$  and  $F_2$  from  $C$  to  $\mathbb{R}^n$ ) have  $D = C$  and mean that  $F_1 - \mu_1 H$  and  $F_2 - \mu_2 H$  are monotone on  $C$  or, equivalently for  $i = 1, 2$ , that

$$\langle F_i(x') - F_i(x), x' - x \rangle \geq \mu_i \langle x' - x, H[x' - x] \rangle \quad \text{when } x, x' \in C,$$

while  $\tilde{F}_1 = F_1 - \mu_1 H$  is Lipschitz continuous on  $C$  with constant  $\tilde{\kappa}_1$  from  $\|\cdot\|_H$  to  $\|\cdot\|_{H^{-1}}$ . For the maximal monotonicity of  $T_2 = F_2 + N_C$ , see Rockafellar [40, Theorem 3].

The introduction in (A) of a Lipschitz constant not for  $T_1$  but the residual mapping  $\tilde{T}_1 = T_1 - \mu_1 H$  may seem odd, but it's crucial to our strategy of trying to separate the convergence analysis of forward-backward splitting methods from certain "unessential" features of the splitting. This will be clarified in section 3. For practical purposes there's no disadvantage, at least, by virtue of the following fall-back estimate.

**PROPOSITION 2.1** (Lipschitz estimate). *Suppose  $\kappa_1$  is a Lipschitz constant for  $T_1$  itself on  $D$  from the norm  $\|\cdot\|_H$  to the norm  $\|\cdot\|_{H^{-1}}$ :*

$$\|T_1(x') - T_1(x)\|_{H^{-1}} \leq \kappa_1 \|x' - x\|_H \quad \text{for all } x', x \in D.$$

*Then  $\kappa_1 \geq \mu_1$ , and the value  $\sqrt{\kappa_1^2 - \mu_1^2}$  is a Lipschitz constant for  $\tilde{T}_1 = T_1 - \mu_1 H$  on  $D$  with respect to the same norms. Thus, one can always take  $\tilde{\kappa}_1 = \sqrt{\kappa_1^2 - \mu_1^2}$  in the absence of anything better.*

*Proof.* By squaring both sides of the Lipschitz inequality given by  $\kappa_1$ , we can write

$$\begin{aligned} \kappa_1^2 \|x' - x\|_H^2 &\geq \|T_1(x') - T_1(x)\|_{H^{-1}}^2 = \|(\tilde{T}_1 + \mu_1 H)(x') - (\tilde{T}_1 + \mu_1 H)(x)\|_{H^{-1}}^2 \\ &= \|\tilde{T}_1(x') - \tilde{T}_1(x) + \mu_1 H[x' - x]\|_{H^{-1}}^2 \\ &= \|\tilde{T}_1(x') - \tilde{T}_1(x)\|_{H^{-1}}^2 + 2\mu_1 \langle H[x' - x], H^{-1}[\tilde{T}_1(x') - \tilde{T}_1(x)] \rangle \\ &\quad + \mu_1^2 \langle H[x' - x], H^{-1}H[x' - x] \rangle \\ &= \|\tilde{T}_1(x') - \tilde{T}_1(x)\|_{H^{-1}}^2 + 2\mu_1 \langle x' - x, \tilde{T}_1(x') - \tilde{T}_1(x) \rangle + \mu_1^2 \|x' - x\|_H^2. \end{aligned}$$

Here  $\langle x' - x, \tilde{T}_1(x') - \tilde{T}_1(x) \rangle \geq 0$  because  $\tilde{T}_1$  is monotone by assumption. Hence

$$\|\tilde{T}_1(x') - \tilde{T}_1(x)\|_{H^{-1}}^2 \leq (\kappa_1^2 - \mu_1^2) \|x' - x\|_H^2.$$

Because this holds for all  $x$  and  $x'$  in  $D$  and  $D$  has more than one point, it's apparent that  $\kappa_1 \geq \mu_1$  and that  $\sqrt{\kappa_1^2 - \mu_1^2}$  serves as a Lipschitz constant  $\tilde{\kappa}_1$  for  $\tilde{T}_1$  on  $D$ .  $\square$

We develop next a technical fact which will repeatedly be brought into play.

**PROPOSITION 2.2** (inverse Lipschitz continuity from strong monotonicity). *If a mapping  $T_0 : \mathbb{R}^n \rightrightarrows \mathbb{R}^n$  is maximal monotone and  $T_0 - \mu_0 H$  is monotone for some  $\mu_0 > 0$  where  $H$  is symmetric and positive definite, then  $T_0^{-1}$  is single valued and Lipschitz continuous, with  $\mu_0^{-1}$  serving as a Lipschitz constant from the  $\|\cdot\|_{H^{-1}}$  metric to the  $\|\cdot\|_H$  metric.*

*Proof.* Whenever  $w \in T_0(x)$  and  $w' \in T_0(x')$  we have by assumption that

$$\begin{aligned} 0 &\leq \langle [w' - \mu_0 Hx'] - [w - \mu_0 Hx], x' - x \rangle \\ &= \langle w' - w, x' - x \rangle - \mu_0 \langle H[x' - x], [x' - x] \rangle \\ &\leq \|x' - x\|_H \|w' - w\|_{H^{-1}} - \mu_0 \|x' - x\|_H^2. \end{aligned}$$

Thus,  $\|x' - x\|_H \leq \mu_0^{-1} \|w' - w\|_{H^{-1}}$  whenever  $x' \in T_0(w')$  and  $x \in T_0^{-1}(w)$ , so that  $T_0^{-1}(w)$  can't contain more than one point, and  $T_0^{-1}$  is Lipschitz continuous on its effective domain with constant  $\mu_0^{-1}$  and in particular is locally bounded everywhere. But  $T_0^{-1}$  inherits maximal monotonicity from  $T_0$ , so the latter necessitates  $T_0^{-1}$  being nonempty valued everywhere, cf. Rockafellar [41].  $\square$

**THEOREM 2.3** (algorithmic background). *Under (A) the mapping  $T = T_1 + T_2$  is maximal monotone and also strongly monotone. There is a unique solution  $\bar{x}$  to  $0 \in T(\bar{x})$ , and for any  $\lambda > 0$  the iteration mapping  $S_\lambda$  is single valued and Lipschitz continuous from the set  $D = \text{dom } T$  into itself, with unique fixed point  $\bar{x}$ .*

*Proof.* Although the single-valued mapping  $T_1$  need not be defined outside of  $D$ , it at least has (through Lipschitz continuity) a unique continuous extension  $T'_1$  to the closed convex set  $C = \text{cl } D$ , this extension being monotone and having the same Lipschitz constant as  $T_1$ . We can enlarge  $T'_1$  to a maximal monotone mapping  $T''_1 : \mathbb{R}^n \rightrightarrows \mathbb{R}^n$  by defining  $T''_1(x) = T'_1(x) + N_C(x)$  when  $x \in C$  but  $T''_1(x) = \emptyset$  when  $x \notin C$ , cf. Rockafellar [40, Theorem 3]. Since  $\text{dom } T''_1 = C = \text{cl}(\text{dom } T_2)$ , the relative interiors of  $\text{dom } T''_1$  and  $\text{dom } T_2$  have nonempty intersection (they actually coincide). Then, because  $T_2$  like  $T''_1$  is maximal monotone, it follows that  $T''_1 + T_2$  is maximal monotone, cf. Rockafellar [40, Theorem 2]. To deduce that  $T$  is maximal monotone, it suffices therefore to demonstrate that  $T''_1(x) + T_2(x) = T_1(x) + T_2(x)$  for all  $x \in C$  or, in other words, that  $T_2(x) + N_C(x) \subset T_2(x)$  for all  $x \in C$ . Unless actually  $x \in D$ , this holds trivially with both sides empty.

For any  $x \in D$  and  $w \in T_2(x)$ , we have  $\langle x' - x, w' - w \rangle \geq 0$  whenever  $w' \in T_2(x')$ ; also, for any  $u \in N_C(\hat{x})$ , we have  $\langle x' - x, u \rangle \leq 0$  for all  $x' \in C$ . Consequently, we have  $\langle x' - x, w' - (w + u) \rangle \geq 0$  whenever  $w' \in T_2(x')$ . The maximal monotonicity of  $T_2$  then implies  $w + u \in T_2(x)$ ; if it doesn't, the pair  $(x, w + u)$  could be added to the graph of  $T_2$  to get a properly larger mapping that is still monotone. Therefore,  $T_2(x) + N_C(x) \subset T_2(x)$  for all  $x \in D$ , as required. Thus,  $T$  is maximal monotone.

From the representation  $T = (T_1 - \mu_1 H) + (T_2 - \mu_2 H) + (\mu_1 + \mu_2)H$  with  $\mu_1 + \mu_2 > 0$ , where the first two terms are monotone by assumption, we have  $T - (\mu_1 + \mu_2)H$  monotone. Because  $H$  is itself strongly monotone, as a consequence of being positive definite,  $T$  likewise is strongly monotone. Hence  $T^{-1}$  is single valued and Lipschitz continuous by Proposition 2.2. In particular the set  $T^{-1}(0)$ , which consists of the solutions  $\bar{x}$  to  $0 \in T(\bar{x})$ , has to be a singleton.

Turning now to the properties of  $S_\lambda$ , we observe first that the mapping  $\lambda T_2$ , like  $T_2$  itself, is maximal monotone and has the same effective domain as  $T_2$ , the relative interior of which meets that of the mapping  $x \mapsto Hx$  (namely,  $\mathbb{R}^n$ ). Furthermore, the latter mapping, by virtue of linearity and positive definiteness, is maximal monotone, even strongly monotone. It follows through [40, Theorem 2] that  $H + \lambda T_2$  is maximal monotone. Moreover, the mapping  $[H + \lambda T_2] - (1 + \lambda \mu_2)H$  is monotone, so by Proposition 2.2 the mapping  $(H + \lambda T_2)^{-1}$  must be single valued everywhere and Lipschitz continuous. In fact, it has constant  $(1 + \lambda \mu_2)^{-1}$  from  $\|\cdot\|_{H^{-1}}$  to  $\|\cdot\|_H$ . At the same time the mapping  $H - \lambda T_1$  is single valued and Lipschitz continuous on  $D$  under (A), and, therefore,  $S_\lambda$ , the composite of these two mappings, is of such type as well.

The condition  $x = S_\lambda(x)$  corresponds to having  $[H - \lambda T_1](x) \in [H + \lambda T_2](x)$  and hence to having  $-T_1(x) \in T_2(x)$ , which is the same as  $0 \in T(x)$ . Therefore, the unique fixed point of  $S_\lambda$  on  $D$  is the unique  $\bar{x}$  with  $0 \in T(\bar{x})$ .  $\square$

**THEOREM 2.4** (global contraction rate). *Under (A) and for any  $\lambda > 0$ , the value*

$$(2.4) \quad \theta_\lambda = \begin{cases} \frac{\sqrt{(1 - \lambda \mu_1)^2 + \lambda^2 \tilde{\kappa}_1^2}}{1 + \lambda \mu_2} & \text{when } \lambda^{-1} \geq \mu_1, \\ \frac{\lambda(\tilde{\kappa}_1 + \mu_1) - 1}{1 + \lambda \mu_2} & \text{when } \lambda^{-1} \leq \mu_1, \end{cases}$$

*which depends continuously on  $\lambda$ , is a Lipschitz constant for  $S_\lambda : D \rightarrow D$  as a mapping*

from the  $\|\cdot\|_H$  metric to the  $\|\cdot\|_H$  metric. In particular,

$$\|S_\lambda(x) - \bar{x}\|_H \leq \theta_\lambda \|x - \bar{x}\|_H \quad \text{for all } x \in D,$$

so that  $S_\lambda$  is globally contractive to  $\bar{x}$  on  $D$  when  $\theta_\lambda < 1$ , which is true for all  $\lambda > 0$  sufficiently small, specifically if and only if  $\lambda$  is chosen small enough that

$$(2.5) \quad \lambda^{-1} > \frac{\mu_1 - \mu_2}{2} + \frac{\tilde{\kappa}_1}{2} \max\left\{1, \frac{\tilde{\kappa}_1}{\mu_1 + \mu_2}\right\}.$$

The best such estimated contraction rate,  $\theta_\lambda$ , as  $\lambda$  ranges over these choices, is

$$(2.6) \quad \bar{\theta} = \theta_{\bar{\lambda}} = \frac{1}{\sqrt{1 + \left(\frac{\mu_1 + \mu_2}{\tilde{\kappa}_1}\right)^2}}, \quad \text{for } \bar{\lambda} = \frac{1}{\left(\frac{\tilde{\kappa}_1^2}{\mu_1 + \mu_2}\right) + \mu_1}.$$

*Proof.* As already argued in the proof of Proposition 2.2, our assumptions on  $T_2$  in (A) ensure that  $(H + \lambda T_2)^{-1}$  is single valued and Lipschitz continuous with constant  $(1 + \lambda \mu_2)^{-1}$  from  $\|\cdot\|_{H^{-1}}$  to  $\|\cdot\|_H$ . Since  $S_\lambda = (H + \lambda T_2)^{-1}(H - \lambda T_1)$ , our task in establishing the Lipschitz constant  $\theta_\lambda$  for  $S_\lambda$  comes down to showing that the second factor in the formula for  $\theta_\lambda$  serves as a Lipschitz constant for  $H - \lambda T_1$  on  $D$  from  $\|\cdot\|_H$  to  $\|\cdot\|_{H^{-1}}$ . Fix any points  $x$  and  $x'$  in  $D$ . In terms of having  $T_1 = \tilde{T}_1 + \mu_1 H$ , we expand

$$(2.7) \quad \begin{aligned} & \|(H - \lambda T_1)(x') - (H - \lambda T_1)(x)\|_{H^{-1}}^2 \\ &= \|(1 - \lambda \mu_1)H - \lambda \tilde{T}_1\|(x') - [(1 - \lambda \mu_1)H - \lambda T_1](x)\|_{H^{-1}}^2 \\ &= \|(1 - \lambda \mu_1)H[x' - x] - \lambda[\tilde{T}_1(x') - \tilde{T}_1(x)]\|_{H^{-1}}^2 \\ &= (1 - \lambda \mu_1)^2 \langle H[x' - x], H^{-1}H[x' - x] \rangle \\ &\quad - 2\lambda(1 - \lambda \mu_1) \langle H[x' - x], H^{-1}[\tilde{T}_1(x') - \tilde{T}_1(x)] \rangle \\ &\quad + \lambda^2 \langle [\tilde{T}_1(x') - \tilde{T}_1(x)], H^{-1}[\tilde{T}_1(x') - \tilde{T}_1(x)] \rangle \\ &= (1 - \lambda \mu_1)^2 \|x' - x\|_H^2 + \lambda^2 \|\tilde{T}_1(x') - \tilde{T}_1(x)\|_{H^{-1}}^2 \\ &\quad - 2\lambda(1 - \lambda \mu_1) \langle x' - x, \tilde{T}_1(x') - \tilde{T}_1(x) \rangle. \end{aligned}$$

At this stage our analysis divides into the cases where  $1 - \lambda \mu_1 \geq 0$  or  $1 - \lambda \mu_1 \leq 0$ , which correspond to  $\lambda^{-1} \geq \mu_1$  or  $\lambda^{-1} \leq \mu_1$ . (When equality holds in these relations the two paths of argument will lead to the same thing.)

In the case where  $1 - \lambda \mu_1 \geq 0$ , we can invoke the fact that  $\langle x' - x, \tilde{T}_1(x') - \tilde{T}_1(x) \rangle \geq 0$  because  $\tilde{T}_1$  is monotone on  $D$ . We then get from (2.7) and the specification of  $\tilde{\kappa}_1$  that

$$\|(H - \lambda T_1)(x') - (H - \lambda T_1)(x)\|_{H^{-1}}^2 \leq (1 - \lambda \mu_1)^2 \|x' - x\|_H^2 + \lambda^2 \tilde{\kappa}_1^2 \|x' - x\|_H^2,$$

hence  $\|(H - \lambda T_1)(x') - (H - \lambda T_1)(x)\|_{H^{-1}} \leq [(1 - \lambda \mu_1)^2 + \lambda^2 \tilde{\kappa}_1^2]^{1/2} \|x' - x\|_H$  in accordance with the first version of  $\theta_\lambda$ . In the case where  $1 - \lambda \mu_1 \leq 0$  instead, we use the inequality

$$\langle x' - x, \tilde{T}_1(x') - \tilde{T}_1(x) \rangle \leq \|x' - x\|_H \|\tilde{T}_1(x') - \tilde{T}_1(x)\|_{H^{-1}} \leq \tilde{\kappa}_1 \|x' - x\|_H^2$$

from (2.3) to argue through (2.7) that

$$\begin{aligned}
& \| (H - \lambda T_1)(x') - (H - \lambda T_1)(x) \|_{H^{-1}}^2 \\
& \leq (1 - \lambda \mu_1)^2 \|x' - x\|_H^2 + \lambda^2 \tilde{\kappa}_1^2 \|x' - x\|_H^2 + 2\lambda(\lambda \mu_1 - 1) \tilde{\kappa}_1 \|x' - x\|_H^2 \\
& \leq [(1 - \lambda \mu_1)^2 + \lambda^2 \tilde{\kappa}_1^2 + 2\lambda(\lambda \mu_1 - 1) \tilde{\kappa}_1] \|x' - x\|_H^2 \\
& = [\lambda(\tilde{\kappa}_1 + \mu_1) - 1]^2 \|x' - x\|_H^2.
\end{aligned}$$

We obtain  $\|(H - \lambda T_1)(x') - (H - \lambda T_1)(x)\|_{H^{-1}} \leq [\lambda(\tilde{\kappa}_1 + \mu_1) - 1] \|x' - x\|_H$  in accordance with the second version of  $\theta_\lambda$ .

In order to understand the nature of the factor  $\theta_\lambda$  better, we begin by observing that for  $\lambda$  large enough that  $\lambda^{-1} \leq \mu_1$ , the function  $\phi(\lambda) = \theta_\lambda = [\lambda(\tilde{\kappa}_1 + \mu_1) - 1]/(1 + \lambda \mu_2)$  has  $\phi'(\lambda) = [\tilde{\kappa}_1 + \mu_1 + \mu_2]/(1 + \lambda \mu_2)^2 > 0$  and hence is an increasing function. In seeking low values of  $\theta_\lambda$  we therefore aren't interested in  $\lambda$  with  $\lambda^{-1} < \mu_1$  and can concentrate on the case of  $\lambda^{-1} \geq \mu_1$ , where the other formula holds for  $\theta_\lambda$ . Note, though, that

$$(2.8) \quad \theta_\lambda < 1 \iff \lambda^{-1} > (\mu_1 - \mu_2 + \tilde{\kappa}_1)/2 \quad \text{when } \lambda^{-1} < \mu_1.$$

The analysis of  $\theta_\lambda$  when  $\lambda^{-1} \geq \mu_1$  is simplified by passing temporarily from  $\lambda$  to the parameter

$$\tau = (\lambda^{-1} + \mu_2)^{-1}, \quad \text{which gives} \quad \tau^{-1} = \lambda^{-1} + \mu_2, \quad \lambda^{-1} = \tau^{-1} - \mu_2.$$

The condition  $\lambda^{-1} \geq \mu_1$  means  $\tau^{-1} \geq \mu$ , where we introduce the notation  $\mu = \mu_1 + \mu_2$  for simplicity. We get

$$(2.9) \quad \theta_\lambda^2 = \frac{(\lambda^{-1} - \mu_1)^2 + \tilde{\kappa}_1^2}{(\lambda^{-1} + \mu_2)^2} = \tau^2 [(\tau^{-1} - \mu)^2 + \tilde{\kappa}_1^2] = 1 - 2\mu\tau + (\tilde{\kappa}_1^2 + \mu^2)\tau^2.$$

From this expression it's obvious that  $\theta_\lambda < 1$  if and only if  $(\tilde{\kappa}_1^2 + \mu^2)\tau^2 < 2\mu\tau$  or, in other words,  $\tau^{-1} > (\tilde{\kappa}_1^2 + \mu^2)/2\mu$ . This condition translates back to  $\lambda^{-1} > [(\tilde{\kappa}_1^2 + \mu^2)/2\mu] - \mu_2 = [\tilde{\kappa}_1^2/2\mu] + (\mu_1 - \mu_2)/2$ , because  $\mu^2 - 2\mu\mu_2 = \mu(\mu_1 + \mu_2 - 2\mu_2) = \mu(\mu_1 - \mu_2)$ . Thus,

$$(2.10) \quad \theta_\lambda < 1 \iff \lambda^{-1} > \frac{\mu_1 - \mu_2}{2} + \frac{\tilde{\kappa}_1^2}{2(\mu_1 + \mu_2)} \quad \text{when } \lambda^{-1} \geq \mu_1.$$

The union of (2.8) with (2.10) furnishes the condition claimed in (2.5) for having  $\theta_\lambda < 1$ .

The expression in (2.9) is a strictly convex function of  $\tau$  which achieves its minimum uniquely when  $-2\mu + 2(\tilde{\kappa}_1^2 + \mu^2)\tau = 0$  or, in other words, the value  $\bar{\tau} = \mu/(\tilde{\kappa}_1^2 + \mu^2)$ . This does have the property that  $\bar{\tau}^{-1} \geq \mu$ , so the associated step size  $\bar{\lambda}$  satisfies  $\bar{\lambda}^{-1} \geq \mu_1$ . The corresponding minimum value for the expression in (2.9) is  $\tilde{\kappa}_1^2/(\tilde{\kappa}_1^2 + \mu^2)$ . Therefore, the lowest achievable value for  $\theta_\lambda$  is  $\theta_{\bar{\lambda}} = \tilde{\kappa}_1/\sqrt{\tilde{\kappa}_1^2 + \mu^2}$  for

$$\bar{\lambda} = 1/(\bar{\tau}^{-1} - \mu_2) = \mu/[(\tilde{\kappa}_1^2 + \mu^2) - \mu\mu_2],$$

which works out to the value claimed for  $\bar{\lambda}$  in the theorem.  $\square$

COROLLARY 2.5 (special rate estimates). *When the estimate  $\tilde{\kappa}_1 = \sqrt{\kappa_1^2 - \mu_1^2}$  is used in accordance with Proposition 2.1, the corresponding best contraction rate that can be guaranteed is*

$$(2.11) \quad \theta_{\bar{\lambda}} = \frac{1}{\sqrt{1 + \frac{(\mu_1 + \mu_2)^2}{\kappa_1^2 - \mu_1^2}}} \quad \text{for } \bar{\lambda} = \frac{\mu_1 + \mu_2}{\kappa_1^2 + \mu_1 \mu_2}.$$

In the case of  $\mu_2 = 0$  this reduces to

$$(2.12) \quad \theta_{\bar{\lambda}} = \sqrt{1 - \left(\frac{\mu_1}{\kappa_1}\right)^2} \quad \text{for } \bar{\lambda} = \frac{\mu_1}{\kappa_1^2}.$$

*Proof.* The case in (2.11) is obvious from Theorem 2.4, and the one in (2.12) then follows by elementary algebra in replacing  $\mu_2$  by 0.  $\square$

The convergence result in Corollary 2.5 was developed in Chen's thesis [37], but Theorem 2.4 itself, with its emphasis on  $\tilde{\kappa}_1$  instead of  $\kappa_1$ , appears here for the first time.

An alternative result of Renaud [32, Proposition VI.25] under the assumption that  $T$  and  $T_1^{-1}$  are strongly monotone gives R-linear convergence. The convergence factor (not necessarily a contraction factor as above) is

$$(2.13) \quad \frac{1}{\sqrt{1 + \frac{\mu\nu_1}{\alpha_{\min}/\alpha_{\max}}}} \quad \text{for } \lambda = \nu_1 \alpha_{\min},$$

where  $\mu$  and  $\nu_1$  are strong monotonicity constants for  $T$  and  $T_1^{-1}$  in the sense of (1.12) and (1.13) (i.e., calibrated by  $I$  instead of  $H$ ), and  $\alpha_{\min}$  and  $\alpha_{\max}$  are the smallest and biggest eigenvalues of  $H$ . (Here we specialize to  $\mathbb{R}^n$ ; Renaud operated in the context of a possibly infinite-dimensional Hilbert space.) Renaud didn't actually require  $\mu$  to be a strong monotonicity constant in the full sense of (1.12) but just a value satisfying

$$(2.14) \quad \langle w - \bar{w}, x - \bar{x} \rangle \geq \mu \|x - \bar{x}\|^2 \quad \text{if } w \in T(x), \quad \text{where } \bar{w} = 0 \in T(\bar{x}).$$

Likewise this would suffice in Theorem 2.4 if we aimed at Q-linear convergence to  $\bar{x}$  instead of insisting that  $S_\lambda$  be a contraction mapping; see section 4.

The dependence of Renaud's factor in (2.13) on  $\alpha_{\min}/\alpha_{\max}$ , which is the condition number of  $H$ , should be noted. This is disadvantageous unless  $H = I$ , so the condition number is 1; see section 3. When  $H = I$  and  $T_1$  is strongly monotone, it's possible under our assumptions to take  $\nu_1 = \mu_1/\kappa_1^2$ . Then Renaud's factor in (2.13) becomes

$$\frac{1}{\sqrt{1 + \frac{\mu_1(\mu_1 + \mu_2)}{\kappa_1^2}}} \quad \text{for } \lambda = \frac{\mu_1}{\kappa_1^2},$$

which isn't as sharp as our factor in Corollary 2.5. On the other hand, if  $\nu_1 > 0$  is known directly one can take  $\kappa_1 = 1/\nu_1$  and get  $1/\sqrt{1 + (\mu_1 + \mu_2)\nu_1}$  in (2.13) in comparison to  $1/\sqrt{1 + [(\mu_1 + \mu_2)\nu_1]^2}$  in Corollary 2.5, where  $\mu_1\nu_1 \leq 1$  but perhaps  $(\mu_1 + \mu_2)\nu_1 > 1$ .

**3. Utilization of strong monotonicity.** A major purpose of our analysis has been to gain insight into how a splitting can be set up advantageously. In expressing  $T$  as a sum  $T_1 + T_2$ , there may be terms that could be assigned either to  $T_1$  or to  $T_2$  without creating an obstacle to the implementation of the forward-backward method. What approach is best in enhancing convergence?

Let's focus on shifts of positive monotonicity. On the basis of (A) we can write  $T = \tilde{T}_1 + \tilde{T}_2 + \mu H$  for  $\tilde{T}_1 = T_1 - \mu_1 H$ ,  $\tilde{T}_2 = T_2 - \mu_2 H$ , and  $\mu = \mu_1 + \mu_2$ . Here  $\tilde{T}_1$  and  $\tilde{T}_2$  are maximal monotone (for if they are not, that would mean the graph of one of them, say  $\tilde{T}_1$ , could be enlarged without destroying monotonicity, in which case the same would be true for  $\tilde{T}_1 + \mu_1 H = T_1$ , contrary to the maximality of  $T_1$ ).

Suppose we were to divide up  $\mu$  in a different way, i.e.,  $\mu = \mu'_1 + \mu'_2$  with  $\mu'_1 \geq 0$  and  $\mu'_2 \geq 0$ , and set  $T'_1 = \tilde{T}_1 + \mu'_1 H$  and  $T'_2 = \tilde{T}_2 + \mu'_2 H$ . This would give a different splitting,  $T = T'_1 + T'_2$ , in which  $T'_1$  and  $T'_2$  are again maximal monotone. Could there be any advantage in this for the algorithm's performance when implemented with the matrix  $H$ ?

The answer is *no* as long as the optimal step size prescription of Theorem 2.4 is employed. This is clear from the fact that the optimal contraction rate  $\bar{\theta}$  in (2.6) depends only on  $\tilde{\kappa}_1$  and the sum  $\mu_1 + \mu_2$  and therefore would be the same under the different splitting, since  $\mu'_1 + \mu'_2 = \mu_1 + \mu_2$  and even  $T'_1 - \mu'_1 H = \tilde{T}_1 = T_1 - \mu_1 H$  (so  $\kappa$  is unaffected). Indeed, the contraction rate has been optimized in Theorem 2.4 with respect to the whole range of splittings that we are looking at. In using the step size  $\bar{\lambda}$  prescribed for the splitting  $T = T_1 + T_2$ , one is able *automatically* to capture whatever algorithmic advantages may lie in this direction. Although the step sizes for the splittings  $T = T_1 + T_2$  and  $T = T'_1 + T'_2$  are given differently as

$$\bar{\lambda} = \frac{1}{\left(\frac{\tilde{\kappa}_1^2}{\mu_1 + \mu_2}\right) + \mu_1}, \quad \bar{\lambda}' = \frac{1}{\left(\frac{\tilde{\kappa}_1^2}{\mu'_1 + \mu'_2}\right) + \mu'_1}$$

and may not themselves be the same, they necessarily result in the same optimal rate  $\bar{\theta}$ .

But a subtle distinction must be noted between Theorem 2.4 and Corollary 2.5. If the tactic in developing a Lipschitz constant for  $\tilde{T}_1$  were to use an estimate based on Proposition 2.1, the answer to the question posed would instead be *yes*!

The reason is that in passing from  $T = T_1 + T_2$  to  $T = T'_1 + T'_2$ , such an estimate  $\tilde{\kappa}_1 = \sqrt{\kappa_1^2 - \mu_1^2}$ , where  $\kappa_1$  is a Lipschitz constant for  $T_1$ , would be replaced by a *different* value  $\tilde{\kappa}'_1 = \sqrt{\kappa'^2_1 - \mu'^2_1}$ , where  $\kappa'_1$  is a Lipschitz constant for  $T'_1$  (relative to the specified norms). Then not only would the corresponding step sizes  $\bar{\lambda}$  and  $\bar{\lambda}'$ , as dictated by (2.11), be different, they would result in different contraction rates:  $\theta_{\bar{\lambda}} \neq \theta_{\bar{\lambda}'}$  in (2.11). The issue would arise of determining which splitting  $T = T'_1 + T'_2$  minimizes  $\sqrt{\kappa'^2_1 - \mu'^2_1}$  and thus furnishes the best contraction rate. Actually, we know from Proposition 2.1 that the minimum is achieved when  $T'_1 = \tilde{T}_1 = T_1 - \mu_1 H$ ,  $T'_2 = \tilde{T}_2 + \mu H = T_2 + \mu_1 H$ . Thus, if we were to rely on the result in Corollary 2.5 rather than the one in Theorem 2.4, as for instance in [37], the optimal splitting would be obtained by extracting all possible strong monotonicity from  $T_1$  and reassigning it to  $T_2$ , a qualitatively very different conclusion.

This highlights the contrast between the technique adopted here and previous research, which has utilized a Lipschitz constant for  $T_1$  itself (moreover one in terms of the canonical norm only), not to speak of concentrating on strong monotonicity of

$T_1$ . Through Theorem 2.4 we can optimally exploit strong monotonicity of  $T_1$  or  $T_2$  or both, without having to switch any terms in the splitting in the end.

The idea is illustrated by its application to solving variational inequalities.

**THEOREM 3.1** (application to projection algorithms). *Consider the variational inequality problem (1.1) in the case of a nonempty, closed convex set  $C \subset \mathbb{R}^n$  and a continuous, single-valued mapping  $F : C \rightarrow \mathbb{R}^n$ . Let  $H$  be a symmetric positive definite matrix, and let  $\mu > 0$  be a constant such that  $F$  satisfies the strong monotonicity condition*

$$(3.1) \quad \langle F(x') - F(x), x' - x \rangle \geq \mu \|x' - x\|_H^2 \quad \text{for all } x, x' \in C.$$

Let  $\tilde{\kappa} \geq 0$  be a Lipschitz constant for  $\tilde{F} = F - \mu H$  on  $C$  from the norm  $\|\cdot\|_H$  to the norm  $\|\cdot\|_{H^{-1}}$ . Then in applying Theorem 2.4 to the splitting  $T = T_1 + T_2$  for  $T_1 = F$ ,  $T_2 = N_C$ , and with  $\mu_1 = \mu$ ,  $\mu_2 = 0$ , the optimal contraction rate is

$$(3.2) \quad \bar{\theta} = \theta_{\bar{\lambda}} = \frac{1}{\sqrt{1 + (\mu/\tilde{\kappa})^2}} \quad \text{for } \bar{\lambda} = \frac{\mu}{\tilde{\kappa}^2 + \mu^2}.$$

No alternative splitting  $T = T'_1 + T'_2$  in the mode of  $T'_1 = F - \tau H$  and  $T'_2 = \tau H + N_C$  for some  $\tau \in (0, \mu]$  can provide a better contraction rate through Theorem 2.4.

*Proof.* This is evident from the preceding remarks. The assumptions furnish a specialization of the conditions in (A) to the special case in question.  $\square$

The fact that under the circumstances described, execution of the forward-backward splitting method as a projection method is just as good as any alternative execution obtainable by shifting the strong monotonicity from the “forward” part to the “backward” part of the iteration mapping, is perhaps surprising. But again, it must be remembered that this result depends on utilizing a Lipschitz constant  $\tilde{\kappa}$  for  $\tilde{F} = F - \mu H$  rather than a constant  $\kappa$  attached directly to  $F$  itself.

**COROLLARY 3.2.** *When the estimate  $\tilde{\kappa} = \sqrt{\kappa^2 - \mu^2}$  is used in Corollary 3.2 in accordance with Proposition 2.1,  $\kappa$  being a Lipschitz constant for  $F$  on  $C$  from  $\|\cdot\|_H$  to  $\|\cdot\|_{H^{-1}}$ , the corresponding best contraction rate that can be guaranteed for the projection algorithm is*

$$(3.3) \quad \theta_{\bar{\lambda}} = \sqrt{1 - \left(\frac{\mu}{\kappa}\right)^2} \quad \text{for } \bar{\lambda} = \frac{\mu}{\kappa^2}.$$

*Proof.* This applies the second part of Corollary 2.5.  $\square$

For the case of  $H = I$ , results related to Corollary 3.2 were obtained recently by Renaud. He noted in [32, p. 143] the contraction rate in (3.3) and went on to demonstrate Q-linear convergence, although not the full contraction property, under the assumption that  $F^{-1}$  is strongly monotone with constant  $\nu > 0$ . The factor is then

$$\frac{1}{\sqrt{1 + \mu\nu}} \quad \text{for } \lambda = \nu,$$

cf. [32, Proposition VI.2]. This alternative assumption is satisfied when  $F$  is Lipschitz continuous with constant  $\kappa$  (from  $\|\cdot\|$  to  $\|\cdot\|$ ), namely with  $\nu = \mu/\kappa^2$ , and Renaud’s factor reduces then to ours.

For the general case where  $H \neq I$ , the contraction rate in Corollary 3.2 may be compared for the one derived for projection algorithms by Dafermos [7]. In effect she

got

$$(3.4) \quad \sqrt{1 - \frac{\mu^2}{\beta_1^2 \beta_2^2 \text{cond}(H)}},$$

where  $\text{cond}(H)$  is the condition number of  $H$  (its highest eigenvalue divided by its lowest eigenvalue),  $\beta_1$  is a conversion factor from  $\|\cdot\|_H$  to  $\|\cdot\|$ , and  $\beta_2$  is a Lipschitz constant for  $F$  from  $\|\cdot\|$  to  $\|\cdot\|_{H^{-1}}$ , so that  $\beta_1\beta_2$  is an (upper) estimate for the Lipschitz constant  $\kappa$  in Corollary 3.2. Unless  $H = I$ , Dafermos' denominator in (3.4) has to be greater than ours in (3.3), and her contraction factor accordingly has to be nearer to 1, thus not as good. The dependence of (3.4) on the condition number for  $H$  illustrates very well the unwarranted consequences of bringing in the canonical norm  $\|\cdot\|$  instead of sticking consistently with the method's intrinsic geometry. The canonical norm is irrelevant in this appraisal of algorithmic performance.

**THEOREM 3.3** (application to affine variational inequalities). *Consider the variational inequality problem (1.1) in the case of a nonempty, closed convex set  $C \subset \mathbb{R}^n$  and an affine mapping  $F(x) = Mx + q$ . Let  $M_s = \frac{1}{2}(M + M^\top)$  and  $M_a = \frac{1}{2}(M - M^\top)$  be the symmetric and antisymmetric parts of the matrix  $M$ , and suppose  $M_s$  is positive definite. Take  $H = M_s$  and define (with the canonical matrix norm)*

$$(3.5) \quad \text{skew}(M) = \|M_s^{-1/2} M_a M_s^{-1/2}\|.$$

*Then Theorem 3.1 applies with  $\mu = 1$  and  $\tilde{\kappa}_1 = \text{skew}(M)$ , which is the minimal Lipschitz constant for this case. The projection algorithm thus attains the global contraction rate*

$$(3.6) \quad \bar{\theta} = \theta_{\bar{\lambda}} = \frac{1}{\sqrt{1 + \frac{1}{\text{skew}(M)^2}}} \quad \text{for } \bar{\lambda} = \frac{1}{1 + \text{skew}(M)^2}.$$

*Proof.* Here  $\tilde{T}_1(x) = (F - \mu H)(x) = M_a x + q$ , an affine monotone mapping devoid of strong monotonicity. We must verify that the specified value of  $\tilde{\kappa}_1$  serves as the minimal Lipschitz constant for this mapping from the norm  $\|\cdot\|_H$  to the norm  $\|\cdot\|_{H^{-1}}$ . The square of the required constant is the supremum of the quotient

$$\frac{\|\tilde{T}_1(x') - \tilde{T}_1(x)\|_{H^{-1}}^2}{\|x' - x\|_H^2} = \frac{\langle M_a[x' - x], M_s^{-1} M_a[x' - x] \rangle}{\langle [x' - x], M_s[x' - x] \rangle} = \frac{\|M_s^{-1/2} M_a[x' - x]\|^2}{\|M_s^{1/2}[x' - x]\|^2}$$

over all  $x$  and  $x'$  with  $x' \neq 0$ . Through the change of variables  $u = M_s^{1/2}[x' - x]$ , giving  $[x' - x] = M_s^{-1/2}u$ , we see that the constant is the supremum of the expression  $\|M_s^{-1/2} M_a M_s^{-1/2} u\|/\|u\|$  over all  $u \neq 0$ , and this is  $\|M_s^{-1/2} M_a M_s^{-1/2}\|$ .  $\square$

The value  $\text{skew}(M) \in (0, \infty)$  in (3.5) intrinsically measures the *skewness* of the matrix  $M$ . Obviously

$$(3.7) \quad \text{skew}(M) \leq \|M_a\|/\|M_s\|$$

in particular, but the right side of this inequality is dependent on the “conditioning” of  $M$  with respect to the canonical norm, whereas  $\text{skew}(M)$  itself isn't. The smaller  $\text{skew}(M)$  is, the nearer  $M$  is to being symmetric and the better the rate of convergence that is assured for the solution method addressed by Theorem 3.3. Of course, this

realization of forward–backward splitting is practical only when it’s easy to project onto  $C$  with respect to the norm induced by  $M_s$  as  $H$ , but that does cover many applications in which  $C$  has a product structure matched by a box-diagonal pattern of  $M_s$ , as in [20].

Dupuis and Darveau [28], in building on the result of Dafermos [7], likewise obtained for the affine variational inequality case of projection algorithms a contraction factor incorporating the value  $\|M_s^{-1/2}M_aM_s^{-1/2}\|$ . But the factor they got resembles the one in (3.4) in being the square root of an expression that depends in part on the condition number of  $H$ . In contrast to our contraction factor in (3.3), it doesn’t tend to 0 as  $M$  approaches symmetry and the implementation matrix  $H = M_s$  coalesces with  $M$ . Again, the cost of deviating from the underlying geometry is evident.

The result in Theorem 3.3 can best be compared with a recent result of Zanni [31] for the same method. He obtains the rate

$$(3.8) \quad \sqrt{1 - \frac{1}{\|M_s^{-1/2}MM_s^{-1/2}\|^2}} \quad \text{for } \lambda = \frac{1}{\|M_s^{-1/2}MM_s^{-1/2}\|^2},$$

which he elaborates by the estimate

$$(3.9) \quad \|M_s^{-1/2}MM_s^{-1/2}\| \leq 1 + \text{cond}(M_s) \frac{\|M_a\|}{\|M_s\|},$$

taking the ratio  $\|M_a\|/\|M_s\|$  as a measure of skewness. The appearance of  $M$  instead of  $M_a$  in (3.8) can be seen as reflecting a reliance on a Lipschitz constant for  $M$  instead of for  $M_a$ ; this parallels the difference between Corollary 3.2 and Theorem 3.1. The estimate in (3.9) suffers from dependence on translation to the canonical norm, but to avoid this it could be replaced by

$$\begin{aligned} \|M_s^{-1/2}MM_s^{-1/2}\| &= \|M_s^{-1/2}(M_s + M_a)M_s^{-1/2}\| \\ &\leq \|M_s^{-1/2}M_sM_s^{-1/2}\| + \|M_s^{-1/2}M_aM_s^{-1/2}\| = 1 + \text{skew}(M). \end{aligned}$$

Even so, it wouldn’t yield the lower contraction factor in Theorem 3.3.

Yet another measure of skewness was introduced by Marcotte and Gu  lat [42] for the special context of solving problems of traffic equilibrium. This differs from ours in being localized to the solution point  $\bar{x}$  and dependent on the vector  $q$  as well as on the submatrices  $M_s$  and  $M_a$ . These authors nonetheless demonstrate through numerical testing of several algorithms an empirical relationship between skewness and difficulty of solvability such as appears in Theorem 3.3.

For projected *gradient* algorithms, where  $F = \nabla f$  for a  $\mathcal{C}^2$  function  $f$  with bounded Hessians  $\nabla^2 f(x)$ , better contraction estimates can be given than are obtainable by specializing the ones here; see Polyak [43].

**4. Local convergence analysis.** Our efforts so far have gone into identifying a rate of linear convergence that’s effective immediately from any starting point  $x_0$  for a forward–backward splitting method. There is interest too, of course, in knowing what might be possible with convergence as the solution  $\bar{x}$  is neared. For this purpose we don’t have to start building up a broader theory but can make use of the results we already have. Although Theorem 2.4 presents a contraction rate relative to the entire set  $D = \text{dom } T$ , its formulation already allows us to deduce local contraction rates in a neighborhood of  $\bar{x}$ .

THEOREM 4.1 (local contraction rates). *Let  $U$  be an open ball around  $\bar{x}$  with respect to the norm  $\|\cdot\|_H$ , and let  $\hat{\mu}_1$ ,  $\hat{\mu}_2$ , and  $\hat{\kappa}_1$  be constants as in (A) but relative to  $D \cap U$  in place of  $D$ . Then, as long as  $\lambda > 0$  is small enough that*

$$(4.1) \quad \lambda^{-1} > \frac{\hat{\mu}_1 - \hat{\mu}_2}{2} + \frac{\hat{\kappa}_1}{2} \max \left\{ 1, \frac{\hat{\kappa}_1}{\hat{\mu}_1 + \hat{\mu}_2} \right\},$$

*the mapping  $S_\lambda$  carries  $D \cap U$  into  $D \cap U$ , and the conclusions of Theorem 2.4 hold for this localization of  $S_\lambda$  but with  $\hat{\mu}_1$ ,  $\hat{\mu}_2$ , and  $\hat{\kappa}_1$  in place of  $\mu_1$ ,  $\mu_2$ , and  $\kappa_1$ .*

*Proof.* Taking  $C = \text{cl } U$ , define  $\hat{T}_2 = T_2 + N_C$ . This mapping, like  $T_2$ , is maximal monotone; cf. [39, Theorem 2]. Proposition 2.1 and Theorem 2.4 are applicable to  $\hat{T} = T_1 + \hat{T}_2$  with respect to the constants  $\hat{\mu}_1$ ,  $\hat{\mu}_2$ , and  $\hat{\kappa}_1$  on  $\hat{D} = \text{dom } \hat{T}_2 = D \cap C$ . In particular,  $\hat{T}^{-1}(0)$  must be a singleton, but because  $\bar{x}$  belongs to the interior of  $C$ , we have  $N_C(\bar{x}) = \{0\}$  and  $\hat{T}(\bar{x}) = T(\bar{x})$ . Hence  $\hat{T}^{-1}(0) = \{\bar{x}\}$ , and the contraction properties given by Theorem 2.4 for the mapping  $\hat{S}_\lambda = (H + \lambda \hat{T}_2)^{-1}(H - \lambda T_1)$  must refer to this same  $\bar{x}$ . Distances from  $\bar{x}$  can then only be decreased under  $\hat{S}_\lambda$ , so  $\hat{S}_\lambda$  must carry  $D \cap U$  into itself.

Consider now any  $x \in D \cap U$  and let  $w = \hat{S}_\lambda(x)$ . As just seen, we have  $w \in D \cap U$ , which implies that  $w$  belongs to the interior of  $C$ , so  $N_C(w) = \{0\}$ . From the definition of  $\hat{S}_\lambda$  we see that

$$(H - \lambda T_1)(x) \in (H + \lambda \hat{T}_2)(w) = (H + \lambda T_2)(w) + N_C(w) = (H + \lambda T_2)(w),$$

hence, in fact,  $w = (H + \lambda T_2)^{-1}(H - \lambda T_1)(x) = S_\lambda(x)$ . This shows that  $\hat{S}_\lambda$  agrees with  $S_\lambda$  on  $D \cap U$ . The conclusions about the behavior of  $\hat{S}_\lambda$  on  $D \cap U$  therefore translate to ones about  $S_\lambda$ .  $\square$

The proof of Theorem 2.4 reveals a way of refining that result and with it Corollary 2.5 and Theorem 4.1. Although the monotonicity of  $T_2 - \mu_2 H$  is fully utilized in obtaining a Lipschitz constant for the factor  $(H + \lambda T_2)^{-1}$  of  $S_\lambda$ , the assumptions in (A) about  $\mu_1$  and  $\tilde{\kappa}_1$  could be weakened if instead of asking for  $S_\lambda$  to be contractive on  $D$  we merely asked for a bound in  $[0, 1]$  on the ratios  $\|S_\lambda(x) - S_\lambda(\bar{x})\|_H / \|x - \bar{x}\|_H$ . The key is just to observe that if the argument for estimating  $\|(H - \lambda T_1)(x') - (H - \lambda T_1)(x)\|_{H^{-1}}$  is applied only to  $\|(H - \lambda T_1)(x) - (H - \lambda T_1)(\bar{x})\|_{H^{-1}}$ , all that one needs from  $\mu_1$  and  $\tilde{\kappa}_1$  is that the mapping  $\tilde{T}_1 = T_1 - \mu_1 H$  satisfies

$$\langle x - \bar{x}, \tilde{T}_1(x) - \tilde{T}_1(\bar{x}) \rangle \geq 0, \quad \|\tilde{T}_1(x) - \tilde{T}_1(\bar{x})\|_{H^{-1}} \leq \tilde{\kappa}_1 \|x - \bar{x}\|_H.$$

Likewise, under these inequalities the estimate in Proposition 2.1 remains valid with respect to a constant  $\kappa_1$  merely satisfying

$$\|T_1(x) - T_1(\bar{x})\|_{H^{-1}} \leq \kappa_1 \|x - \bar{x}\|_H.$$

This refinement appears to offer little advantage in general over the global picture in Theorem 2.4, inasmuch as special properties of  $T_1$  and  $T_2$  around the solution point  $\bar{x}$ , in contrast to other points, can hardly be available in advance of calculating  $\bar{x}$ , which threatens a kind of circularity. Indeed, if the assumption on  $\mu_1$  is weakened, the very existence and uniqueness of  $\bar{x}$  could be thrown into doubt, because Theorem 2.3 might no longer be applicable. Yet in the localized context of Theorem 4.1, the refinement does at least furnish insights into what might be expected of the rate of convergence in the tail of a forward-backward sequence as  $x_k$  nears  $\bar{x}$ . The following is what we get.

THEOREM 4.2 (ultimate linear convergence rate). *Assuming (A), define the constants  $\bar{\mu}_1 \geq 0$ ,  $\bar{\mu}_2 \geq 0$ , and  $\bar{\kappa}_1 \geq 0$  at the unique solution point  $\bar{x}$  by*

$$\begin{aligned}\bar{\mu}_2 &= \limsup_{\substack{w \in T_2(x), w' \in T_2(x') \\ x, x' \rightarrow \bar{x}, x' \neq x}} \frac{\langle x' - x, w' - w \rangle}{\|x' - x\|_H^2}, \\ \bar{\mu}_1 &= \limsup_{\substack{x \rightarrow \bar{x} \\ x \in D, x \neq \bar{x}}} \frac{\langle x - \bar{x}, T_1(x) - T_1(\bar{x}) \rangle}{\|x - \bar{x}\|_H^2}, \\ \bar{\kappa}_1 &= \limsup_{\substack{x \rightarrow \bar{x} \\ x \in D, x \neq \bar{x}}} \frac{\|\bar{T}_1(x) - \bar{T}_1(\bar{x})\|_{H^{-1}}}{\|x - \bar{x}\|_H} \quad \text{for } \bar{T}_1 = T_1 - \bar{\mu}_1 H,\end{aligned}$$

necessarily obtaining  $\bar{\mu}_1 \geq \mu_1$ ,  $\bar{\mu}_2 \geq \mu_2$ , and  $\bar{\kappa}_1 \leq \tilde{\kappa}_1$ ; in fact,  $\bar{\kappa}_1 \leq \sqrt{\tilde{\kappa}_1^2 - (\bar{\mu}_1 - \mu_1)^2}$  (hence  $\bar{\mu}_1 \leq \mu_1 + \tilde{\kappa}_1$ ). Also define

$$\gamma = \liminf_{\substack{(x,u) \rightarrow (\bar{x}, T_1(\bar{x})) \\ -u \in T_2(x)}} \frac{\|u - T_1(\bar{x})\|_{H^{-1}}}{\|x - \bar{x}\|_H},$$

necessarily obtaining  $\gamma \geq \bar{\mu}_2$ . Then for any step size  $\lambda > 0$ , the sequence of points  $x_k$  generated by  $x_k = S_\lambda(x_{k-1})$  from any starting point  $x_0 \in D$  will satisfy

$$(4.2) \quad \limsup_{k \rightarrow \infty} \frac{\|x_k - \bar{x}\|_H}{\|x_{k-1} - \bar{x}\|_H} \leq \begin{cases} \frac{\sqrt{(1 - \lambda \bar{\mu}_1)^2 + \lambda^2 \bar{\kappa}_1^2}}{\sqrt{1 + 2\lambda \bar{\mu}_2 + \lambda^2 \gamma^2}} & \text{when } \lambda^{-1} \geq \bar{\mu}_1, \\ \frac{\lambda(\bar{\kappa}_1 + \bar{\mu}_1) - 1}{\sqrt{1 + 2\lambda \bar{\mu}_2 + \lambda^2 \gamma^2}} & \text{when } \lambda^{-1} \leq \bar{\mu}_1. \end{cases}$$

In particular, this holds for the step size  $\bar{\lambda}$  identified in (2.6) as optimal relative to the globally estimated constants  $\mu_1$ ,  $\mu_2$ , and  $\tilde{\kappa}_1$ .

*Proof.* It's clear from (A) that  $\bar{\mu}_1 \geq \mu_1$  and  $\bar{\mu}_2 \geq \mu_2$ , since the monotonicity of  $T_i - \mu_i H$  on  $D$  corresponds to having  $\langle x' - x, T_i(x') - T_i(x) \rangle \geq \mu_i \|x' - x\|_H^2$  for  $x, x' \in D$ . The verification that  $\bar{\kappa}_1 \leq \tilde{\kappa}_1$  takes more effort. It relies indirectly on the observation above that Proposition 2.1 stays valid when the context is that of points  $x$  compared to  $\bar{x}$  rather than general pairs  $x$  and  $x'$ . If  $\bar{\mu}_1 = \mu_1$ , we have  $\bar{T}_1 = \tilde{T}_1$  and the inequality  $\bar{\kappa}_1 \leq \tilde{\kappa}_1$  is elementary from the definitions, so we can concentrate on the case where  $\bar{\mu}_1 > \mu_1$ .

Consider any  $\delta \in (0, \bar{\mu}_1 - \mu_1)$ . From the definition of  $\bar{\mu}_1$  there's a neighborhood  $Z$  of  $\bar{x}$  consisting of points  $x$  for which  $\langle x - \bar{x}, T_1(x) - T_1(\bar{x}) \rangle \geq (\bar{\mu}_1 - \delta) \|x - \bar{x}\|_H^2$ . This inequality means that for the mapping  $\bar{T}_1^\delta = T_1 - (\bar{\mu}_1 - \delta)H = \bar{T}_1 - \delta H$ ,

$$(4.3) \quad \langle x - \bar{x}, \bar{T}_1^\delta(x) - \bar{T}_1^\delta(\bar{x}) \rangle \geq 0 \quad \text{for } x \in D \cap Z.$$

But  $\bar{T}_1^\delta = \tilde{T}_1 - \tau H$  for  $\tau = \bar{\mu}_1 - \mu_1 - \delta > 0$ . It follows from applying the extended version of Proposition 2.1 to this relation in light of (4.3) that

$$\|\bar{T}_1^\delta(x) - \bar{T}_1^\delta(\bar{x})\|_{H^{-1}} \leq \sqrt{\tilde{\kappa}_1^2 - \tau^2} \|x - \bar{x}\|_H \quad \text{for } x \in D \cap Z.$$

On the other hand, since  $\bar{T}_1^\delta = \bar{T}_1 - \delta H$  and  $\|H[x - \bar{x}]\|_{H^{-1}} = \|H(x - \bar{x})\|_{H^{-1}} = \|x' - x\|_H$ , we know that  $\|\bar{T}_1(x) - \bar{T}_1(\bar{x})\|_{H^{-1}} \leq \|\bar{T}_1^\delta(x) - \bar{T}_1^\delta(\bar{x})\|_{H^{-1}} + \delta \|x - \bar{x}\|_H$ .

This tells us that

$$\|\bar{T}_1(x) - \bar{T}_1(\bar{x})\|_{H^{-1}} \leq \left( \delta + \sqrt{\bar{\kappa}_1^2 - (\bar{\mu}_1 - \mu_1 - \delta)^2} \right) \|x - \bar{x}\|_H \quad \text{for } x \in D \cap Z.$$

Taking the limit in the definition of  $\bar{\kappa}_1$  and using the fact that a neighborhood  $Z$  like this exists for any  $\delta > 0$ , we obtain  $\bar{\kappa}_1 \leq \sqrt{\bar{\kappa}_1^2 - (\bar{\mu}_1 - \mu_1)^2}$ ; hence,  $\bar{\kappa}_1 \leq \bar{\kappa}_1$  because  $\bar{\mu}_1 \geq \mu_1$ .

We look next at the claims about  $\gamma$  and  $\theta_\lambda^*$ , the latter being the symbol by which we'll denote the right side of (4.2). For any  $\epsilon > 0$ , let  $\hat{\mu}_i = \max\{\mu_i, \bar{\mu}_i - \epsilon\}$  for  $i = 1, 2$  and  $\hat{\kappa}_1 = \min\{\bar{\kappa}_1, \bar{\kappa}_1 + \epsilon\}$ . On the basis of the definitions we know there's a ball  $U$  around  $\bar{x}$  with respect to the norm  $\|\cdot\|_H$  such that

$$\begin{cases} \langle x' - x, w' - w \rangle \geq \hat{\mu}_2 \|x' - x\|_H & \text{if } x, x' \in D \cap U, w \in T_2(w), w' \in T_2(x'), \\ \langle x - \bar{x}, T_1(x) - T_1(\bar{x}) \rangle \geq \hat{\mu}_1 \|x - \bar{x}\|_H & \text{if } x \in D \cap U, \\ \|\bar{T}_1(x) - \bar{T}_1(\bar{x})\|_{H^{-1}} \leq \hat{\kappa}_1 \|x - \bar{x}\|_H & \text{if } x \in D \cap U. \end{cases}$$

We are then in the framework of the extended version of Theorem 4.1 and are able to see that  $\limsup_k \|x_k - \bar{x}\|_H / \|x_{k-1} - \bar{x}\|_H \leq \hat{\theta}_\lambda$ , the latter being the same as  $\theta_\lambda$  except that  $\hat{\mu}_1$ ,  $\hat{\mu}_2$ , and  $\hat{\kappa}_1$  replace  $\mu_1$ ,  $\mu_2$ , and  $\bar{\kappa}_1$ . An improvement can be made, however, in taking advantage of the constant  $\gamma$ .

Let  $\hat{\gamma} = \max\{0, \gamma - \epsilon\}$ . From the definition of  $\gamma$  there's a neighborhood  $V$  of  $T_1(\bar{x})$  with respect to the norm  $\|\cdot\|_{H^{-1}}$  such that, when the ball  $U$  is small enough, we have

$$(4.4) \quad \|u - T_1(\bar{x})\|_{H^{-1}} \geq \hat{\gamma} \|x - \bar{x}\|_H^2 \quad \text{when } x \in D \cap U, u \in V, -u \in T_2(x).$$

However, the point  $\bar{u} = T_1(\bar{x})$  also satisfies  $-\bar{u} \in T_2(\bar{x})$  because  $0 \in T(\bar{x}) = T_1(\bar{x}) + T_2(\bar{x})$ . This implies from earlier that

$$\hat{\mu}_2 \|x - \bar{x}\|_H^2 \leq \langle -u + \bar{u}, x - \bar{x} \rangle \leq \|x - \bar{x}\|_H \|u - \bar{u}\|_{H^{-1}},$$

so  $\hat{\mu}_2 \|x - \bar{x}\|_H \leq \|u - \bar{u}\|_{H^{-1}}$ . Therefore,  $\hat{\mu}_2 \leq \hat{\gamma}$ , which establishes  $\bar{\mu}_2 \leq \gamma$  through the arbitrariness of  $\epsilon$  in the definition of  $\hat{\mu}_2$  and  $\hat{\gamma}$ .

Let  $\bar{w} = (H - \lambda T_1)(\bar{x}) = H\bar{x} - \lambda T_1(\bar{x})$ . Since

$$\bar{x} = S_\lambda(\bar{x}) = (H + \lambda T_2)^{-1}(H - \lambda T_1)(\bar{x}),$$

we have  $\bar{x} = (H + \lambda T_2)^{-1}(\bar{w})$ . Consider along with this any elements  $w$  and  $x$  with  $x = (H + \lambda T_2)^{-1}(w)$ . For these, the set  $T_2^{-1}(x)$  contains  $\lambda^{-1}[w - Hx]$ , whereas  $T_2^{-1}(\bar{x})$  contains  $\lambda^{-1}[\bar{w} - H\bar{x}]$ , the latter being just  $-T_1(\bar{x})$ . When  $w$  is close to  $\bar{w}$ , not only does  $x$  lie in the ball  $U$  around  $\bar{x}$ , due to the continuity of  $(H + \lambda T_2)^{-1}$ , but also the vector  $u = -\lambda^{-1}[w - Hx]$  lies in the neighborhood  $V$  of  $\bar{u} = -T_1(\bar{x})$ . Then by (4.4),

$$\begin{aligned} \hat{\gamma}^2 \|x - \bar{x}\|_H^2 &\leq \|u - T_1(\bar{x})\|_{H^{-1}}^2 = \|\lambda^{-1}[w - Hx] + \lambda^{-1}[\bar{w} - H\bar{x}]\|_{H^{-1}}^2 \\ &= \lambda^{-2} \|w - \bar{w}\|_{H^{-1}}^2 - 2\lambda^{-2} \langle w - \bar{w}, x - \bar{x} \rangle + \|x - \bar{x}\|_H^2 \\ &\leq \lambda^{-2} \|w - \bar{w}\|_{H^{-1}}^2 - 2\lambda^{-2} \hat{\mu}_2 \|x - \bar{x}\|_H^2 + \lambda^{-2} \|x - \bar{x}\|_H^2, \end{aligned}$$

where the last inequality invokes the property arranged for  $\hat{\mu}_2$ . Rearranging, we obtain  $\|x - \bar{x}\|_H^2 \leq [1 + \lambda \hat{\mu}_2 + \lambda^2 \hat{\gamma}^2] \|w - \bar{w}\|_{H^{-1}}^2$ . This shows that the factor  $(1 + \lambda \hat{\mu}_2)^{-1}$  in  $\hat{\theta}_\lambda$  can be replaced by  $(1 + \lambda \hat{\mu}_2 + \lambda^2 \hat{\gamma}^2)^{-1/2}$ , which if anything is lower.

It remains only to observe that, having demonstrated that this modified factor  $\hat{\theta}_\lambda$  operates in terms of  $\hat{\mu}_1$ ,  $\hat{\mu}_2$ ,  $\hat{\kappa}_1$ , and  $\hat{\gamma}$  as defined for arbitrary  $\epsilon > 0$ , we must in the limit as  $\epsilon \searrow 0$  get the factor  $\theta_\lambda^*$  corresponding to  $\bar{\mu}_1$ ,  $\bar{\mu}_2$ ,  $\bar{\kappa}_1$ , and  $\gamma$ .  $\square$

**5. Variable step sizes and matrices.** In the introduction, forward-backward splitting methods were described with variable step sizes  $\lambda_k$  and matrices  $H_k$ . We now look at what can be said about such methods on the basis of our contraction results for fixed  $\lambda$  and  $H$ . The easier case of variable  $\lambda_k$  with a fixed  $H$  has broader significance, so we deal with it first.

**THEOREM 5.1** (convergence with variable step sizes). *Under assumptions (A), consider any step size interval  $[\lambda_-, \lambda_+] \subset (0, \infty)$  with  $\lambda_+$  small enough that*

$$(5.1) \quad \lambda_+^{-1} > \frac{\mu_1 - \mu_2}{2} + \frac{\tilde{\kappa}_1}{2} \max \left\{ 1, \frac{\tilde{\kappa}_1}{\mu_1 + \mu_2} \right\}.$$

*Let  $\theta(\lambda_-, \lambda_+) = \max\{\theta_{\lambda_-}, \theta_{\lambda_+}\}$  for  $\theta_\lambda$  defined as in (2.4). Then  $\theta(\lambda_-, \lambda_+) < 1$ , and for any sequence of step sizes  $\lambda_k \in [\lambda_-, \lambda_+]$ , all the iteration mappings*

$$(5.2) \quad S_k = (H + \lambda_k T_2)^{-1}(H - \lambda_k T_1) = (I + \lambda_k H^{-1} T_2)^{-1}(I - \lambda_k H^{-1} T_1)$$

*are contractions from  $D = \text{dom } T$  into itself with fixed point  $\bar{x}$  and contraction factor  $\theta(\lambda_-, \lambda_+)$ . In particular, the iterates  $x_k = S_k(x_{k-1})$  from any starting point  $x_0 \in D$  converge linearly to  $\bar{x}$  at a rate no worse than  $\theta(\lambda_-, \lambda_+)$ . Indeed,*

$$(5.3) \quad \limsup_{k \rightarrow \infty} \frac{\|x_k - \bar{x}\|_H}{\|x_{k-1} - \bar{x}\|_H} \leq \min \{ \theta(\lambda_-, \lambda_+), \theta^*(\lambda_-, \lambda_+) \},$$

*where  $\theta^*(\lambda_-, \lambda_+) = \min\{\theta_{\lambda_-}^*, \theta_{\lambda_+}^*\}$  with  $\theta_\lambda^*$  denoting the right side of (4.2).*

*Proof.* The justification of this lies in the proof of Theorem 2.4. It was demonstrated there that  $\theta_\lambda$  is an increasing function of  $\lambda$  on the interval of  $\lambda$  values satisfying  $\lambda^{-1} < \mu_1$ , which includes all  $\lambda$  sufficiently large. On the other hand, it was observed that on the complementary interval, where  $\lambda^{-1} \geq \mu_1$ , the expression  $\theta_\lambda^2$  is convex as a function of  $\tau$  under the change of variables induced by taking  $\tau^{-1} = \lambda^{-1} + \mu_2$ . This implies that  $\theta_\lambda^2$  is unimodal on that interval with respect to  $\lambda$ , and the same then holds for  $\theta_\lambda$ . Indeed, we saw for the value  $\bar{\lambda}$  defined in (2.6) that  $\theta_\lambda$  is a continuous, decreasing function of  $\lambda$  on  $(0, \bar{\lambda}]$  but a continuous, increasing function of  $\lambda$  on  $[\bar{\lambda}, \infty)$ .

It follows that the max of  $\theta_\lambda$  over any interval  $[\lambda_-, \lambda_+] \subset (0, \infty)$  is  $\theta(\lambda_-, \lambda_+)$ . As long as this value doesn't exceed 1, as guaranteed by (5.1) through Theorem 2.4, we get contraction at the claimed rate  $\theta(\lambda_-, \lambda_+)$ . An appeal to the ultimate convergence property in Theorem 4.2 then justifies the assertion in (5.3).  $\square$

For the case of variable implementation matrices, we won't attempt to prove a result along the lines of a Newton or quasi-Newton method. That would be incompatible with most applications of forward-backward splitting to problem decomposition, where the need to preserve a degree of separability, in order to facilitate computation of the backward steps, is paramount. Also, such applications tend to demand a global statement rather than a local one. For literature on Newton-like results for variational inequalities, see Pang and Chan [16] and Patriksson [17].

**THEOREM 5.2** (convergence with variable matrices). *Under (A), suppose the iterates  $x_k = S_k(x_{k-1})$  are generated from any  $x_0 \in D$  by the mappings*

$$(5.4) \quad S_k = (H_k + \lambda_k T_2)^{-1}(H_k - \lambda_k T_1) = (I + \lambda_k H_k^{-1} T_2)^{-1}(I - \lambda_k H_k^{-1} T_1)$$

*through a sequence of step sizes  $\lambda_k > 0$  and symmetric, positive definite matrices  $H_k$  converging to  $H$ . Let  $\lambda_- = \liminf_k \lambda_k$  and  $\lambda_+ = \limsup_k \lambda_k$ , and suppose that  $\lambda_- > 0$  while  $\lambda_+$  satisfies (5.1). Then (5.3) holds for these values  $\lambda_-$  and  $\lambda_+$ .*

*Proof.* The convergence of  $H_k$  to  $H$  implies the existence of values  $0 < \alpha_k \nearrow 1$  and  $0 < \beta_k \nearrow 1$  such that  $H - \alpha_k H_k$  and  $H_k - \beta_k H$  are positive definite. Through this, the monotonicity of  $T_1 - \mu_1 H$  and  $T_2 - \mu_2 H$  in condition (2.1) of (A) yields the monotonicity of  $T_1 - \mu_{1k} H_k$  and  $T_2 - \mu_{2k} H_k$  for the values  $\mu_{1k} = \mu_1 \alpha_k \nearrow \mu_1$  and  $\mu_{2k} = \mu_2 \alpha_k \nearrow \mu_2$ .

We develop now a Lipschitz constant for  $\tilde{T}_{1k} = T_1 - \mu_{1k} H_k = \tilde{T}_1 + \mu_1 (H - \alpha_k H_k)$  from the norm  $\|\cdot\|_{H_k}$  to the norm  $\|\cdot\|_{H_k^{-1}}$ . First, let  $\eta_k$  be such a constant for  $H - \alpha_k H_k$ , then  $\eta_k \rightarrow 0$ . Next, observe that  $\|\cdot\|_{H_k} \geq \sqrt{\beta_k} \|\cdot\|_H$ , which means that for the corresponding dual norms given by the inverse matrices,  $\sqrt{\beta_k} \|\cdot\|_{H_k^{-1}} \leq \|\cdot\|_{H^{-1}}$ . By these estimates, the Lipschitz inequality in condition (2.2) of (A) gives us

$$\sqrt{\beta_k} \|\tilde{T}_1(x') - \tilde{T}_1(x)\|_{H_k^{-1}} \leq \tilde{\kappa}_1 (1/\sqrt{\beta_k}) \|x' - x\|_{H_k} \quad \text{for all } x', x \in D.$$

Hence  $\tilde{\kappa}_1/\beta_k$  is a Lipschitz constant for  $\tilde{T}_1$  on  $D$  from  $\|\cdot\|_{H_k}$  to  $\|\cdot\|_{H_k^{-1}}$ . Since  $\tilde{T}_{1k} = \tilde{T}_1 + \mu_1 (H - \alpha_k H_k)$ , we conclude that the constant  $\tilde{\kappa}_{1k} = (\tilde{\kappa}_1/\beta_k) + \mu_1 \eta_k \searrow \tilde{\kappa}_1$  has this property for  $\tilde{T}_{1k}$ .

It follows that the splitting  $T = T_{1k} + T_{2k}$  with implementation matrix  $H_k$  satisfies (A<sub>k</sub>), the version of (A) in which  $\mu_1$ ,  $\mu_2$ , and  $\tilde{\kappa}_1$  are replaced by  $\mu_{1k}$ ,  $\mu_{2k}$ , and  $\tilde{\kappa}_{1k}$ . Now let  $\phi$  stand for the value on the right side of (2.5) and  $\phi_k$  for the corresponding value under this same replacement of constants. Obviously  $\phi_k \rightarrow \phi$ .

Consider any  $\epsilon > 0$  small enough that the value  $\lambda_-^\epsilon = \lambda_- - \epsilon$  is positive, while the value  $\lambda_+^\epsilon = \lambda_+ + \epsilon$  satisfies (5.1); i.e.,  $(\lambda_+^\epsilon)^{-1} > \phi$ . For all  $k$  sufficiently large, we have  $\lambda_k \in [\lambda_-^\epsilon, \lambda_+^\epsilon]$  and also that  $(\lambda_+^\epsilon)^{-1} > \phi_k$ . Then by Theorem 2.4 as applied under (A<sub>k</sub>), the mapping  $S_k$  is a contraction from  $D$  into itself at the rate  $\theta_{k,\lambda_k}$ , where  $\theta_{k,\lambda}$  denotes the factor obtained from formula (2.4) with  $\mu_{1k}$ ,  $\mu_{2k}$ , and  $\tilde{\kappa}_{1k}$  substituting for  $\mu_1$ ,  $\mu_2$ , and  $\tilde{\kappa}_1$ . Furthermore, we have

$$\theta_{k,\lambda} \leq \theta_k(\lambda_-^\epsilon, \lambda_+^\epsilon) = \max\{\theta_{k,\lambda_-^\epsilon}, \theta_{k,\lambda_+^\epsilon}\}$$

for the reasons in the proof of Theorem 5.1 (when applied to  $\theta_{k,\lambda}$  as a function of  $\lambda$ ). Therefore, the lim sup in (5.3) is bounded above by the limit of  $\theta_k(\lambda_-^\epsilon, \lambda_+^\epsilon)$  as  $k \rightarrow \infty$ , which is  $\theta(\lambda_-^\epsilon, \lambda_+^\epsilon)$ . This being valid for all  $\epsilon > 0$  sufficiently small, we can take the limit as  $\epsilon \searrow 0$  and obtain the inequality in (5.3), as targeted.  $\square$

**6. Asymmetric implementations.** Only symmetric implementation matrices  $H_k$  are covered directly by our results up to this stage, but what about the possibility of more general matrices that are not symmetric, although still positive definite? Such modes of implementation crop up, for example, in applications to variational inequality when  $H_k$  is taken to be an approximation to the Jacobian matrix  $\nabla F(x_k)$  or some part of it. Aside from the gradient case where  $F = \nabla f$  and  $\nabla F(x_k) = \nabla^2 f(x_k)$ ,  $H_k$  may then lack symmetry.

Asymmetric implementation matrices can be incorporated into our theory by a simple device. This device has already been used by others, e.g., Tseng in [25], but we go beyond previous instances because of the attention we pay to step sizes. To explain the idea, we keep to the case of constant  $H$  for simplicity. Also, to avoid conflicts with our earlier statements, we follow the notational strategy of replacing  $H$  by  $H + K$  with  $K$  antisymmetric ( $K^\top = -K$ ) and  $H$  still symmetric, rather than taking  $H$  itself to lack symmetry. This conforms to the fact that any positive definite matrix can be written as the sum of an antisymmetric matrix and a symmetric, positive definite matrix.

In this mode, the iteration mappings for the forward-backward method with respect to a splitting  $T = T_1 + T_2$  take the form

$$(6.1) \quad ([H + K] + \lambda T_2)^{-1}([H + K] - \lambda T_1).$$

Their practicality hinges on the ease of calculating images under the inverse mapping  $([H + K] + \lambda T_2)^{-1}$ . This has to be assumed for any analysis to be worthwhile, and it's true that in applications such have been pinpointed by Pang and Chan [16] and Tseng [25].

For our purposes we'll make such practicality of backward step execution part of the framework by assuming that for any  $\tau \in (-\infty, \infty)$ , the inverse  $([H + \tau K] + \lambda T_2)^{-1}$  can be handled just as readily as  $([H + K] + \lambda T_2)^{-1}$ . We put our focus therefore on *two-parameter* iteration mappings, namely

$$(6.2) \quad S_{\lambda, \tau} = ([H + \tau K] + \lambda T_2)^{-1}([H + \tau K] - \lambda T_1).$$

These mappings, like the earlier ones where  $K$  didn't appear, all have the unique solution  $\bar{x}$  as their unique fixed point. We explore the relation between contraction properties of  $S_{\lambda, \tau}$  and the values of both  $\lambda$  and  $\tau$ .

**THEOREM 6.1** (reduction of asymmetric to symmetric implementations). *Assume (A) as before, except for what it says about  $\tilde{\kappa}_1$ ; in place of that, consider a Lipschitz constant  $\tilde{\kappa}_1(\sigma)$  for the mapping  $\hat{T}_1 - \sigma K$  on  $D$ , with  $\sigma$  being any value in  $(-\infty, \infty)$ . Let*

$$(6.3) \quad \lambda(\sigma) = \frac{1}{\left(\frac{\tilde{\kappa}_1(\sigma)^2}{\mu_1 + \mu_2}\right) + \mu_1}, \quad \tau(\sigma) = \sigma \lambda(\sigma).$$

*Then the asymmetrically implemented iteration mapping*

$$(6.4) \quad S_{\lambda(\sigma), \tau(\sigma)} = ([H + \tau(\sigma)K] + \lambda(\sigma)T_2)^{-1}([H + \tau(\sigma)K] - \lambda(\sigma)T_1),$$

*with respect to the splitting  $T = T_1 + T_2$ , is identical to the symmetrically implemented iteration mapping*

$$(6.5) \quad S'_{\lambda(\sigma)} = (H + \lambda(\sigma)T'_2)^{-1}(H - \lambda(\sigma)T'_1),$$

*with respect to the splitting  $T = T'_1 + T'_2$ , where  $T'_1 = T_1 - \sigma K$  and  $T'_2 = T_2 + \sigma K$ , and it is Lipschitz continuous on  $D$  with constant*

$$(6.6) \quad \theta(\sigma) = \frac{1}{\sqrt{1 + \left(\frac{\mu_1 + \mu_2}{\tilde{\kappa}_1(\sigma)}\right)^2}} < 1.$$

*Proof.* Iterations  $x_k = S_{\lambda, \tau}(x_{k-1})$  have the meaning that

$$0 \in \frac{1}{\lambda}[H + \tau K][x_k - x_{k-1}] + T_1(x_{k-1}) + T_2(x_k).$$

This condition can equally well be written as

$$(6.7) \quad 0 \in \frac{1}{\lambda}H[x_k - x_{k-1}] + [T_1 - \sigma K](x_{k-1}) + [T_2 + \sigma K](x_k)$$

under the correspondence  $\sigma = \tau/\lambda$ ,  $\tau = \sigma\lambda$ . Thus, the same iterations can be written as  $x_k = S'_\lambda(x_{k-1})$  for  $S'_\lambda = (H + \lambda T'_2)^{-1}(H - \lambda T'_1)$ . The splitting  $T = T'_1 + T'_2$  satisfies (A) with Lipschitz constant  $\tilde{\kappa}_1(\sigma)$ , so Theorem 2.4 applies. The optimal step size coming out of that result is  $\lambda(\sigma)$  as given by (6.3), and it yields for  $S'_{\lambda(\sigma)}$  the contraction rate  $\theta(\sigma)$  defined in (6.6).  $\square$

The observation to be made from Theorem 6.1 is that instead of pursuing asymmetric implementations directly, a good strategy is to first subtract off from  $T_1$  to get  $T'_1$  whatever multiple  $\sigma$  of the asymmetric part  $K$  of the implementation matrix  $H+K$  is appropriate in order to reduce the Lipschitz constant  $\tilde{\kappa}_1(\sigma)$  as far as possible. This multiple is added to  $T_2$  to get  $T'_2$ . Thereafter, it's just a matter of taking the optimal step size  $\lambda(\sigma)$  for the altered splitting  $T = T'_1 + T'_2$  with respect to the symmetric part  $H$  of the implementation matrix, in accordance with the earlier results. The net effect will be the same as the asymmetric iterations (6.4) but executed symmetrically and at an optimized rate.
